Staphylococcus aureus is a ubiquitous organism on warm-blooded animals and its presence in low numbers in raw foods of animal origin is to be expected. Although most strains isolated from animals do not produce enterotoxins, some do, and not infrequently strains of human origin (Biotype A), which are the main enterotoxin producers, will be found on foods of animal origin. It is important, therefore, to avoid the use for further processing of raw materials that may be contaminated with large numbers of *S. aureus*, as although the organism may be killed by such processing, enterotoxins may be present and these are unlikely to be removed or destroyed. Also the handling of such contaminated raw materials in a food processing environment is likely to lead to their establishment in that environment, and/or to become a source of contamination of other products. It is particularly important to control raw materials that are likely to be sources of *S. aureus* if these are to be used in a process, such as raw-milk cheese or fermented sausage manufacture, where further multiplication may occur.

One of the main sources of contamination of foods with *S. aureus* is without doubt the food handler. It is therefore important that all food handlers are made aware of the importance of good personal hygiene and of the need to report any skin infections to management so that the infections may be treated.

Staphylococcus aureus needs appropriate growth conditions to form its enterotoxins. Most foods, and many raw materials and ingredients, will support growth and enterotoxin formation given the right conditions, the most important of which are time and temperature. If such conditions exist in any part of the food chain, it is important to ensure that either the product will not support the growth of *S. aureus* or that the organism is eliminated by appropriate processing and that the product is then protected from potential sources of recontamination. Whereas processing (eg, heating) may eliminate *S. aureus* cells, it will not destroy any enterotoxin formed by growth of the organism prior to processing. Therefore, it is important to avoid significant growth prior to processing.

The application of the Hazard Analysis Critical Control Point (HACCP) to a particular food-processing or food-handling operation is the only certain way to determine whether the presence of *S. aureus* is potentially a hazard in a foodstuff produced under a particular production regime, and to establish what control measures may be needed; see Chapter 58 for the use of HACCP.

47.10 CONCLUDING REMARKS

Despite well-defined methods of control, principally based on the application of good hygienic practice, staphylococcal food poisoning remains a significant cause of foodborne illness in many parts of the world. Recognizing that the source of most strains of *S. aureus* causing gastroenteritis is the human carrier, better education and training of food handlers are likely to have the most impact on such illness.

The heightened medical concerns arising from the increasing occurrence of antibiotic-resistant strains of *S. aureus* does not require food producers to apply additional measures to control these organisms as they are not more resistant than other strains to the sanitizers and other procedures used by the food industry to kill this organism. However, the continued, widespread use of antibiotics during the growing of food animals must inevitably lead to an increased risk of antibiotic-resistant strains of *S. aureus* entering the food chain, infecting humans, and further adding to the already serious clinical problems caused by these organisms.

48.1 INTRODUCTION

The preponderance of historical information regarding the genus *Vibrio* centers on *Vibrio cholerae* because of the catastrophic events that have occurred as a result of this organism. Prior to the mid 1900s, the organism responsible for cholera was the only human pathogen placed eventually in the taxonomic position that we know today. Since cholera has affected millions of individuals worldwide during the past two centuries, the intensive research of its cause and prevention is more than justified. Only in the last 50 years have most of the other species now included in this genus been identified. This resulted from the recognition that several unidentified organisms were responsible for human illness and also from the environmental occurrence of organisms appearing to be related to *V. cholerae.* Due to the extensive amount of literature regarding the many species of *Vibrios* and due to space constraints, this chapter is a summary of the current information on the more common pathogenic species. This chapter will deal mainly with the major foodborne pathogens *V. cholerae, V. parahaemolyticus,* and *V. vulnificus*, with an emphasis on aspects of major concern to food microbiologists. Detailed reviews of pathogenic vibrios can be found in many studies.[72,119,120,127,168,170]

Man's association with the bacterium now called *Vibrio cholerae* began many centuries ago. Cholera was mentioned in ancient writings nearly 2,500 years ago[110] and was the term given to any type of gastrointestinal disorder, particularly those with resultant diarrhea. The causative agent of cholera was first described in Italy in 1854 by Pacini.[132] He discovered that the intestinal contents of cholera victims contained large numbers of a curved bacterium that he called *Vibrio cholera.* His discovery was overshadowed by that of Robert Koch, who demonstrated while studying the disease in Egypt in 1883 that cholera was caused by a comma-shaped organism. He called the organism "Kommabazillen" and the name *Vibrio comma* was used for several decades. Pacini's work was finally recognized and *Vibrio cholerae,* Pacini 1854, was designated as the type species of the genus. Cholera has afflicted millions of individuals over the centuries and has been one of the most feared bacterial diseases of man, with the exception of the bubonic plague of the 18th century in Europe and Asia Minor. The disease has also been called Asiatic cholera, because the organism subsequently was determined to be endemic in that region and responsible for large epidemics in the Ganges basin of India and Bangladesh. The population of the Bengal region has not been free of the disease in recent times. Cholera is spread rapidly among individuals after drinking water and food have become contaminated because of inadequate sewage disposal and poor sanitation. Cholera epidemics have been associated primarily with underprivileged, low socioeconomic populations lacking potable water sources. Crowded living conditions aid the rapid spread of the disease. Pandemic waves have occurred along trade routes and in association with pilgrimage and migration.

Seven pandemics have been recorded since the early 19th century (Table 48–1). The first six originated on the Indian subcontinent and ended about 1925. The seventh pandemic is notable in that it originated in Indonesia in 1961 and has endured for more than 30 years. This pandemic spread through Southeast Asia, into Asia and the Middle East, and reached the African continent in 1970. Twenty years later cholera reached the South American continent, which had been free of the disease for more than a century. From the initial cases in Peru in January 1991, the epidemic spread rapidly to bordering countries and into Central America. Accumulatively, from January 1991 through June 1994, the Pan American Health Association recorded well over 1 million cases of cholera in 20 South and Central American countries and close to 10,000 deaths.[164] These figures include cases imported into the United States (US) and the United Kingdom (UK). The seventh pandemic is the most notable of those recorded in that it has been the most extensive in geographic spread and in duration.[77]

In the fall of 1992, an explosive epidemic originated in the Bengal region of India from a previously unknown serogroup of *V. cholerae*.[3] All aspects of this epidemic were similar to that caused by the O1 serogroup. This new serogroup was designated O139 and the strain as "Bengal." This epidemic spread through India, eventually to Bangladesh, Nepal, Burma, Pakistan, Thailand, China, Malaysia, and Saudi Arabia. Imported cases also were reported in the UK and the US. The epidemic afflicted thousands of individuals and caused many deaths. The Bengal strain was found to share many virulence features with the El Tor biotype of O1 *V. cholerae* of the seventh pandemic. Because of the similarity of disease, O139 Bengal is considered to be the second etiological agent of cholera. Due to its spread to other countries within a 2-year period, some suggest it is the eighth cholera pandemic (Table 48–1).[77,159]

Two other more notable foodborne human pathogenic species are *V. parahaemolyticus*, first identified in 1950 as the cause of gastroenteritis from consumption of contaminated dried sardines,[55] and *V. vulnificus*, an organism first isolated from a wound infection and described as a lactose-positive vibrio,[68] then given species designation in 1979.[48] *V. parahaemolyticus* has caused several large outbreaks of gastroenteritis from the consumption of contaminated seafood. This species can be considered as the leading cause of seafoodborne bacterial gastroenteritis, causing numerous individual cases besides the large recorded outbreaks.[126,137,168] *V. vulnificus* is considered to be one of the most invasive and rapidly lethal of human pathogens described.[127] Infections start with a gastrointestinal disorder and rapidly progress to a septicemic condition. *V. vulnificus* has received a tremendous amount of press coverage in the US in the past de-

cade because of the high mortality caused in medically impaired individuals.

A majority of the *Vibrio* spp. have been identified more recently. Of the 34 species currently recognized, most were given species designation after 1950.[8] Molecular characterization of a number of these species has resulted in recent proposals to reclassify some either to a newly named genus or to a different one that already exists. Illnesses attributed to many of these species are rare and most likely have to do with host susceptibility. Most of these species cause sporadic, isolated illness and have not caused major outbreaks involving large numbers of individuals. The virulence mechanisms and the route of infection of several of these species have yet to be identified.

48.2 TAXONOMY AND CHARACTERISTICS OF *VIBRIO*

48.2.1 General Aspects

The family Vibrionaceae was first proposed in 1965 by Veron[7] to group organisms into genera that generally were oxidase-positive and motile by means of a polar flagellum. This grouping was not intended to imply ancestral relationship, but to differentiate the organisms from the Enterobacteriaceae and the recognized human pathogens in that group. Oxidase activity is the important character in differentiation of vibrios from the other common enteric pathogens. Most species in liquid media have a single, sheathed, polar flagellum. On solid media, some produce lateral, unsheathed flagella, which are essential for swarming on solid media. The family currently contains four genera: *Vibrio*, *Aeromonas*, *Plesiomonas*, and *Photobacterium*. *Vibrio* are Gram-negative, nonsporeforming, straight or curved rods and facultative anaerobes with both respiratory and fermentative metabolism.[8] All use D-glucose as a sole source of carbon and energy and most use ammonium salts as a sole nitrogen source. Bioluminescence has been observed in some species.

Vibrios are abundant in the aquatic environment. Several cause disease in humans as well as in marine vertebrates and invertebrates, such as fish, eels, and mollusks. Of the 34 currently recognized species, 12 have been associated with human infections. The disease spectra attributed to these 12 species are presented in Table 48–2.

Growth of all vibrios is stimulated by sodium ions, in concentrations of 5 to 700 mM. Most require 2% to 3% NaCl or a seawater base for optimum growth. Tolerance of various levels of NaCl in laboratory medium is used as a basis for species identification. Vibrios can be divided into two groups based on this requirement, those not requiring the addition of NaCl to laboratory media—*V. cholerae* and *V. mimicus*—and the remaining 32 halophilic species that require media supplemented with NaCl.

Many species tolerate moderately alkaline conditions, with growth at pH 9, and some at pH 10. They do not tolerate acidic conditions and some rapidly decline in numbers at pH 5 or less. Vibrios are also

sensitive to the vibriostatic agent O/129 (2,4-diamino-6,7-diisopropylpteridine), although the sensitivity differs between species. The sensitivity patterns are used in the differentiation of species.

A few exceptions in characteristics are notable for the food microbiologist. *V. metschnikovii* is the only species that is oxidase-negative. *V. furnissii* and *V. gazogenes* are the only aerogenic species, differing from the other species by producing gas during fermentation of glucose. It has also been reported that the O139 serogroup of *V. cholerae* is resistant to vibriostatic agent O/129.[77]

The biochemical properties of the clinically important species are published in a number of reference manuals.[8,44,84,109] Table 48–3 presents a list of the biochemical features for differentiation of the food-associated *Vibrio* pathogens and two other common seafood-associated organisms in the family Vibrionaceae (*Aeromonas hydrophila* and *Plesiomonas shigelloides*). *Vibrio* species can be grouped initially according to sucrose fermentation and the color reaction obtained on the sucrose-based thiosulfate-citrate-bile salts-sucrose agar (TCBS). *V. cholerae, V. fluvialis, V. furnissii, V. alginolyticus,* and *V. metschnikovii* are sucrose-positive. The sucrose-negative group includes *V. parahaemolyticus, V. mimicus, V. vulnificus,* and *V. hollisae,* although strain variability has been reported for some of these.

Source: Adapted from E.L. Elliot et al., *V. Cholerae, V. Parahaemolyticus, V. Vulnificus* and Other *Vibrio* Spp. in *Bacteriological Analytical Manual, 8th ed.,* pp. 9.01–9.27, A.O.A.C. International, Gaithersburg, Maryland, Food and Drug Administration.

Arginine dihydrolase and lysine decarboxylase activity are also useful to further differentiate the pathogenic species.

48.2.2 Serotyping of *V. cholerae*

Two important properties that identify epidemic *V. cholerae* are the production of cholera toxin (CT) and the somatic serogroup. Currently more than 150 serogroups have been identified antigenically and the majority of environmental strains encountered are in serogroups other than O1 and O139. The O1 serogroup has, until recently, been exclusively linked with epidemic and pandemic cholera. Until the emergence of the newly designated O139 serogroup, isolates identified as *V. cholerae* that would not agglutinate in O1 antiserum were reported as non-O1 *V. cholerae*. The determination of serogroups other than O1 and O139 is impractical; the more recent literature now refers to these as non-O1/O139 strains.

The O1 serogroup can be subdivided into the Ogawa, the Inaba, and the very rare Hikojima serotypes. The serotype distinction has been used for epidemiological purposes; however, recent reports indicate that serotype conversion can occur, so this distinction may prove of limited value. *V. cholerae* O1 also can be divided into two biotypes, classical and El Tor, based on hemolytic ability. Classical strains are nonhemolytic, while El Tor strains produce a beta-hemolysin detectable on sheep blood agar plates. Several other laboratory tests can be used to differentiate the O1 biotypes besides hemolytic ability, including a Voges-Proskauer reaction, inhibition by polymyxin B, agglutination of chicken erythrocytes, and a phage typing system.[8,44,84,109] The nonhemolytic classical strains are believed to be the cause of the first six pandemics and are endemic on the Indian subcontinent (Table 48–1). The El Tor biotype is responsible for the seventh pandemic, currently is the more prevalent of the biotypes, and is endemic in several areas of the world. Classical strains are isolated infrequently in Bangladesh since the advent of the seventh pandemic, seemingly being replaced by the El Tor biotype. The O139 serogroup is also hemolytic, resembling El Tor strains.

48.2.3 Serotyping of *V. parahaemolyticus*

The only other pathogenic species for which an extensive serotyping system has been developed is *V. parahaemolyticus*. There are currently 12 O (lipopolysaccharide) and 65 K (acidic polysaccharide) antigens recognized in Japan.[168] Many of the environmental and some clinical isolates are untypable by K antigen, but usually can be grouped by the O antigen. Pathogenic strains occur in each of the O groups, while a common O group may occur more frequently in patients in certain geographical regions.[2,82] While serotyping may be important for epidemiological purposes, commercial antisera are available only from Japanese manufacturers. In addition, they are too costly for most laboratories to purchase and, therefore, are not in use routinely.

48.3 CHARACTERISTICS OF DISEASES

48.3.1 *V. cholerae*

Cholera, recently reviewed in detail,[77] has an incubation period from several hours to 5 days after ingestion of food or water contaminated with toxigenic *V. cholerae*, dependent in part on the inoculum level. The infective dose of *V. cholerae* is believed to be about 1 million cells. Approximately 10^{11} cfu in buffered saline were necessary to induce diarrhea in volunteers;[101] however, only 10^6 cfu ingested in a sodium bicarbonate solution to neutralize stomach acid induced diarrhea. Volunteer feeding studies using 10^6 cfu in food such as rice and fish resulted in a 100% attack rate. This suggests that the ingested food can buffer the gastric acid, enabling the organism to reach and colonize the intestinal tract. *V. cholerae* multiplies in the small intestine and produces cholera toxin. A known predisposition to severe infections is hypochlorhydria.

Typical cholera is characterized by the sudden onset of vomiting and painless diarrhea, with the characteristic "rice-water" stools caused by the presence of mucous. This is followed by suppressed renal function, thirst, leg and abdominal cramping, and collapse due to marked dehydration and resultant electrolyte imbalance. Vomiting is common in patients, occurring a few hours after the onset of diarrhea. Profuse secretory diarrhea is the main symptom with resulting life-threatening dehydration. The fluid loss is so dramatic that an infected person can die within hours. These severe cases, cholera gravis, are reported to afflict about 15% of those infected by the classical strain and only about 2% infected by the El Tor biotype during the epidemics. Mild cases and asymptomatic infections occur most often. Moderate cases requiring medical attention occur in about 15% of those infected with the classical strains and only about 5% of those with El Tor infections. An infected person sheds millions of these organisms in their feces; thus the disease can spread rapidly in areas with poor sanitation and poor hygienic practices. Person-to-person contact has not been substantiated as a cause of spread of the disease. Immediate treatment by rapid infusion of intravenous fluids is usually successful for the advanced cases. Oral rehydration is generally used for the milder cases and has been described as one of the most important therapeutic interventions developed in the 20th century. Antimicrobial therapy, usually with tetracycline, has also been effective in shortening the duration of infection and reducing the carrier state; however, widespread use of antimicrobials is strongly discouraged due to development of resistant strains of the organism. Cholera initiates an immune response in humans and evidence exists for substantial infection-derived immunity. Several vaccines have been developed and some show promise for prevention of future epidemics. An easily administered vaccine, delivered orally, is desired. Currently, live, attenuated bacteria, killed whole-cell preparations, whole cell toxoids, and a Salmonella-based carrier of *V. cholerae* antigens are being evaluated in clinical trials.

There is an increasing number of reports during the past few decades that non-O1/O139 *V. cholerae* strains also cause human diarrheal illness and other clinical manifestations.[119,120] Gastroenteritis is the most common of the illnesses reported; however, these strains have also been isolated from wound and ear infections. Raw oyster consumption is correlated highly with the gastrointestinal infections. The great majority of non-O1/O139 strains do not produce CT and they are not associated with epidemics. Two foodborne outbreaks of gastroenteritis have been reported as caused by non-O1/O139 *V. cholerae*,[120] and there are numerous individual reports of illness implicating consumption of raw shellfish.[137] Gastroenteritis cases occur predominantly during the summer and fall months, accompanying the increased presence of these organisms in the environment. Generally, non-O1/O139 gastroenteritis is reported to be mild or moderate in severity; however, occasionally a severe cholera-like disease has been reported. Symptoms include diarrhea, abdominal cramps, fever, and less frequently, nausea and vomiting. There is no distinguishing symptom that would differentiate these infections from other gastrointestinal infections. Severe dehydration has been reported in a few cases. Duration of illness can be from 1 to 10 days and hospitalization and rehydration have been required for severe cases.

Non-O1/O139 strains have also been isolated from cases of septicemia.[123,138] The source of these infections was not identified in several of these cases. A few patients reported a recent history of seafood consumption or an association with seawater. The fatality rate reported for these cases is over 60%. Epidemiological evidence from some cases suggests that septicemia could be acquired by invasion through the intestinal tract, similar to invasion by *V. vulnificus* (discussed below). Several of these patients had underlying medical conditions that probably made them more susceptible to an invasive infection by rare strains of *V. cholerae*. Strains isolated from septicemic cases are reported to be heavily encapsulated.

48.3.2 *V. parahaemolyticus*

Gastroenteritis is also caused by *V. parahaemolyticus*. First identified in Japan,[55] this species has been the principal cause of foodborne gastroenteritis in that country for many years. Gastroenteritis caused by this species has been linked exclusively to consumption of contaminated seafood.[168] The illness usually begins acutely with explosive diarrhea and cramping abdominal pain, but subsides spontaneously within 48 to 72 hours. The incubation period ranges from 8 to 72 hours, with a median of about 18 hours. Other symptoms, reported in descending frequency, include nausea, vomiting, headache, low-grade fever, and chills. The organism causes damage to the gut mucosa and colonic ulceration; therefore, fecal leukocytes and the organism are found in stools. The mortality rate is quite low, death usually occurring only in the case of elderly or debilitated patients. A severe, dysenteric form of infection and bloody diarrhea occur occasionally. Severe cases of gastroenteritis may require hospitalization, although most are treatable with supportive therapy such as rehydration. Treatment with tetracycline has proven beneficial in cases of prolonged infection. *V. parahaemolyticus* rarely, if ever, invades the bloodstream. Volunteer feeding studies in Japan suggest that ingestion of 2×10^5 to 3×10^7 cells of the thermostable direct hemolysin-producing (TDH) strains are necessary to cause disease.[143]

48.3.3 *V. vulnificus*

V. vulnificus is an invasive species, and epidemiological evidence has clearly demonstrated an association between primary septicemia and the consumption of raw oysters.[127] This bacterium can induce a high fever, usually within 24 hours of ingestion, in susceptible hosts and results in a mortality rate exceeding 50%. The incubation period ranges from 7 h to several days. The most common symptoms include fever, chills, nausea, and hypotension. Symptoms typical of gastroenteritis including abdominal pain, vomiting, and diarrhea are reported more infrequently. The organism commonly becomes localized in the lower extremities with resultant necrosis in advanced cases. Untreated, death can occur within 3 to 5 days. To a great extent, survival depends on prompt antibiotic therapy, tetracycline being the most effective. For many of these infections, prolonged hospitalization was required for those surviving the disease. Surgical debridement and limb amputation were often necessary. Epidemiological evidence has identified individuals with an underlying, chronic disease to be at greatest risk from infection. Common medical histories include liver- or blood-related disorders such as alcoholic cirrhosis and hemochromatosis, which result in elevated serum iron levels. Other risk factors identified include gastric disease, renal disease, diabetes, and use of immunosuppressive agents. One specific susceptible group identified includes males over the age of 40 who abuse alcohol and consume raw oysters. The infective dose of this pathogen for the at-risk individual is unknown. Infections differ from those due to organisms causing true gastroenteritis in that large outbreaks have not been reported. An individual case usually occurs within a group of people or a family that may have consumed a particular lot of shellfish.

Wound infections caused by *V. vulnificus* range from mild to severe, some with rapidly progressive cellulitis and myositis.[127] These infections have occurred as a result of exposure to seawater. Antibiotic treatment of these wound infections with tetracycline has been successful. Again, surgical debridement often is necessary.

48.3.4 Other *Vibrio* spp.

Within the past 15 years, several newly designated species of *Vibrio* have been recognized as human pathogens, including *V. mimicus.*[31] This organism was formerly classified as an atypical, sucrose-negative variant of *V. cholerae.* Gastrointestinal isolates have been recovered from diverse geographical locations.[72] Raw oyster consumption was the most common suspect vehicle of transmission. Onset of symptoms was usually within 24 hours but ranged from 3 to 73 hours. Duration of some cases was as long as 10 days. The symptoms reported were diarrhea, nausea, vomiting, and abdominal cramps. Several cases of ear infection caused by this species have also been reported following exposure to seawater.

V. fluvialis[98] was described in 1981 and has been isolated occasionally from diarrheic stools. Most of the patients suffering diarrhea caused by this species had food histories that included raw oysters, although shrimp and cooked fish also have been implicated. Symptoms were similar to those of other intestinal infections by vibrios except for the frequent occurrence of bloody stools, suggesting possible invasiveness. *V. furnissii*, an aerogenic species closely related to *V. fluvialis*, was given species designation in 1983.[21] *V. furnissii* has been implicated in a few outbreaks of food-related gastroenteritis;[72] however, there is little clinical information concerning the role this species plays in diarrheal illness.

V. hollisae, first described in 1982,[63] has been isolated occasionally from diarrheic stools. The infection in most of these cases has, again, been associated with the consumption of raw molluscan shellfish.[1] Bacteremia has been reported in two instances although the source of these infections could not be identified. Most patients also had underlying medical conditions that probably increased susceptibility to infection. This species grows poorly or not at all on the selective agar TCBS, so in some clinical investigations this species may be inadvertently missed during specimen examination.

V. alginolyticus[139] is one of the most commonly isolated species from seafood and the marine environment, often at high levels. On rare occasions, it has been implicated in gastrointestinal illness[73] but is more commonly associated with wound and ear infections.[72] It has also been isolated from a respiratory infection. Virulence properties have not been defined and it is another vibrio whose role in seafoodborne illness is still unclear.

First described in 1888 and further characterized by Lee et al.,[99] *V. metschnikovii* has been isolated from seafood, river water, and sewage and from human stools, blood, urine, gall bladder, and a leg wound. This species' role as an agent of gastroenteritis has not been established. No evidence exists of the organism causing enteritis. Bacteremia has been reported occasionally but with limited case histories and the rare occurrence of severe illness,[61] it is difficult to determine whether the diseases caused by this species were food-related.

Because there are only two reported cases of infection by *V. cincinnatiensis*,[20] it is not clear whether this is a food-related pathogen. Both patients reported no prior contact with seafood or seawater. One case was of bacteremia and meningitis and the other of enteritis. Both patients were elderly and immunocompromised. The source of the organism was never determined.

Most of the human infections mentioned above are quite rare; however, these species are common in the aquatic environment. Clinicians and food microbiologists should be aware of these organisms and the possible illnesses they can cause. From a food standpoint, these organisms are not generally considered during routine analysis. Continued studies may show that these species contribute to gastrointestinal illnesses and identify potential virulence mechanisms.

48.4 MECHANISMS OF PATHOGENICITY

48.4.1 *V. cholerae*

CT, or choleragen, is perhaps the most intensively studied of any of the toxins. The ability of *V. cholerae* strains to produce CT is the major determinant of virulence. Isolates producing CT are considered fully virulent, are capable of causing epidemic cholera and should be reported as such. A toxin was first proposed in the late 1800s by Koch, but it was not until 1959 that a toxin was demonstrated by two groups working independently.[32,43] Ten years later Finkelstein and LoSpalluto[51] purified the toxin. This enabled further investigations of structure, receptor binding, and mode of action.

CT is a heat-labile protein toxin, composed of a single A and five B subunits, with an approximate molecular weight of 85,000 daltons.[77] The initial action of CT is binding of the B subunit to the receptor, ganglioside G_{m1}, on the cell membrane of epithelial cells. This binding is enhanced by the enzyme neuraminidase produced by *V. cholerae.* The A subunit, after proteolytic cleavage to two further subunits, stimulates adenylate cyclase, resulting in increased cellular levels of cyclic adenosine monophosphate (cAMP). Increased cAMP concentration leads to increased Cl^- secretion by intestinal crypt cells and decreased NaCl absorption by villus cells, resulting in electrolyte movement into the lumen. The resultant osmotic gradient causes water flow to the lumen. The massive water flow overwhelms the absorptive capacity of the intestine, resulting in diarrhea. Further mechanisms also may be involved in the secretory effects of CT. Prostaglandins and the enteric nervous system both respond to CT and may add to the secretion that occurs with this disease.

In addition to CT, *V. cholerae* O1 strains produce other toxins.[77] Zonal occludens toxin (ZOT) increases permeability of the small intestinal mucosa by decreasing tissue resistance of the intercellular tight junction, zonal occludens. It is hypothesized that ZOT causes diarrhea as a result of leakage of water and electrolytes into the lumen by hydrostatic pressure due to the increase in permeability. Sequences of the *zot* gene have subsequently been found in non-O1 strains. Accessory cholera toxin (ACE) causes fluid accumulation in ligated rabbit ileal loops and is suspected of forming an ion channel after its insertion into the epithelial cell membrane. The genes encoding these two toxins, *zot* and *ace*, are located immediately upstream of the *ctx* genes encoding CT in what has been termed a "virulence cassette." The hemolysin that differentiates the El Tor from classical strains is cytolytic to a variety of erythrocytes and mammalian cells in culture, is lethal to mice, causes fluid accumulation in ligated rabbit ileal loops, and is also produced by non-O1 strains. This hemolysin/cytolysin may play an accessory role in diarrhea produced by these strains. Volunteer feeding studies have shown that *ctx* gene-deleted O1 strains can still elicit mild to moderate diarrhea in some individuals; thus, these other toxins may be responsible for the diarrheal cases from which CT-negative strains were recovered. Other reported toxins produced by O1 strains include a "new cholera toxin," a sodium channel inhibitor, and a Shiga-like toxin. Some non-O1/O139 strains produce a heat-stable toxin, referred to as Nag-ST, similar to that produced by the enterotoxigenic *Escherichia coli.* The role of these toxins in human pathogenesis is unknown at present although they may contribute in part to diarrhea caused by strains that do not produce CT.

V. cholerae must first colonize the small intestine to begin the disease process. The toxin coregulated pilus, TCP, is the most characterized colonization factor of this organism. These pili consist of long filaments that are laterally associated in bundles. Expression of the pilus is correlated with the expression of CT; hence the name. Another potential colonization factor, accessory colonization factor, has been described and may be involved in colonization via motility and/or chemotaxis, but its exact nature is still under study. The polar flagellum of *V. cholerae,* besides being involved in motility, may serve as an adhesin and an important virulence factor. In response to chemotaxins, motile *V.*

cholerae are drawn to the mucosal surface of the intestine. Nonmotile but fully toxigenic strains show a markedly diminished virulence in animal models. The production of at least four hemagglutinins by *V. cholerae* has been reported and these may be involved in cellular adherence in the gut. Other possible adherence factors that have been described include outer membrane proteins (OMPs), the lipopolysaccharide (LPS) of the O1 strains, a polysaccharide capsule of non-O1 strains, and other pili. A siderophore, vibriobactin, is also produced by *V. cholerae* but is not necessary for virulence.

There are several systems for regulation of virulence genes in *V. cholerae.* The most extensively characterized regulon is ToxR, which controls expression of CT, the TCP colonization factor, the accessory colonization factor, two OMPs, and three lipoproteins. The control of 17 distinct genes by ToxR has been reported and it is called the "master switch." Volunteers fed a mutated *toxR* gene *V. cholerae* strain did not show diarrheal symptoms.

The virulence mechanisms of the occasional non-O1/O139 strains of *V. cholerae* associated with human infections remain unidentified for the most part. Strain-to-strain variability in virulence occurs within this group of organisms. Most strains fed to volunteers failed to produce illness. Inoculum levels of clinical non-O1/O139 strains greater than 10^6 were necessary to induce diarrhea in volunteers,[119] seemingly a greater number than required for the toxigenic O1 strains. No toxins unique to these serogroups have been described, although some produced by O1 strains and other species have been reported; for example, the hemolysin/cytolysin of the El Tor biotype and the thermostable direct hemolysin gene, *tdh*, of *V. parahaemolyticus* (discussed below). Some strains produce a heat-stable enterotoxin, Nag-ST (mentioned above), and a cholera-like toxin. A few non-O1/O139 strains possess the genes encoding CT, ZOT, and ACE. Other possible virulence factors reported are a Shiga-like toxin, various cell-associated hemagglutinins, and a polysaccharide capsule that could facilitate production of septicemia in susceptible hosts. Some strains of O139 *V. cholerae* have also been reported to produce a polysaccharide capsule, unlike the O1 serogroup. The production of multiple virulence factors by non-O1/O139 *V. cholerae* appears to be necessary to elicit a diarrheal illness, although host susceptibility may play an important role. However, case reports indicate that these bacteria have also caused gastroenteritis in healthy individuals as well as people with preexisting diseases.

48.4.2 *V. parahaemolyticus*

Stool isolates of *V. parahaemolyticus* from patients suffering gastroenteritis produced a beta-hemolysin under specific laboratory conditions.[116] This hemolysin was discovered by researchers in Japan; its production is termed the Kanagawa phenomenon and the strain is often reported as Kanagawa positive or KP+. More than 95% of clinical strains produced this hemolysin, characterized as a TDH. In contrast, only 1% of environmental strains in early studies produced TDH. The production of this hemolysin is detected by plating on a special high salt agar, Wagatsuma agar, containing freshly collected and washed human or sheep erythrocytes.[44,161] Various animal erythrocytes, but not those of horses, are lysed by TDH. TDH is an extracellular protein of approximate molecular weight 44,000 daltons with an apparent subunit structure. The mechanism of action is not understood. This hemolysin is lethal to adult mice on injection, causes fluid accumulation in mouse and rabbit intestines, and has other cytolytic and cardiotoxic abilities.[116,161] Using a KP+ strain and its isogenic KP– mutant, it was demonstrated that only the KP+ parent strain induced fluid accumulation in the rabbit ileal loop assay. When the *tdh* gene was replaced in the isogenic mutant, restoration of secretory activity was observed.

TDH was encoded by one or more nonidentical copies of the *tdh* gene, *tdh*1 and *tdh*2.[124] The predicted protein products differed slightly in amino acid residues, but the proteins were indistinguishable immunologically. KP+ strains contained two gene copies, while KP– or the weakly hemolytic strains only contained one gene copy. The KP phenotype and more than 90% of TDH produced under laboratory conditions were attributable to expression of the *tdh*2 copy. Several other *tdh* gene sequences have since been determined. The regulation of expression of these genes by a regulator similar to the ToxR of *V. cholerae* has been reported recently.[124]

A second hemolysin called the thermostable direct related hemolysin (TRH) was produced by strains of *V. parahaemolyticus* isolated from patient stools from an outbreak in Maldives.[69] These strains did not produce TDH. Two *trh* genes have since been sequenced and TRH has been purified. This hemolysin has characteristics similar, but not identical, to those of TDH.[70] Several clinical isolates of *V. parahaemolyticus* possessed both *trh* and *tdh* genes, but some strains possessed only the *trh* or only the *tdh* gene. Most of the environmental isolates examined contained neither gene. Illnesses previously reported as being caused by KP– strains possibly could be attributed to the production of this hemolysin. Development of an immunological test for TRH production, and a gene probe or polymerase chain reaction (PCR) procedure to detect presence of the *trh* gene, will aid in the assessment of potential virulence of strains of *V. parahaemolyticus* encountered in clinical specimens or seafood.

Several adhesion factors have been proposed for *V. parahaemolyticus*; among them are the lateral flagella, pili, a cell-associated hemagglutinin, and an OMP. The production of a siderophore has also been demonstrated. Further investigation into colonization factors and other virulence mechanisms of *V. parahaemolyticus* is needed.

A correlation has been reported between urease production and the presence of the *tdh* gene in strains of *V. parahaemolyticus* in the Pacific Northwest of the US.[82] All the strains from clinical and environmental samples that possessed *tdh* were urease-producing, but not all urease-producing strains possessed *tdh*. The production of urease may enhance the virulence of some bacteria. Urease was responsible for acid resistance by *Yersinia enterocolitica*.[33] The enzyme may contribute to virulence by enhancing the passage of the organism through the stomach, resisting gastric acid. Although this increase in acid resistance has not been demonstrated for *V. parahaemolyticus*, urease production may protect the organism during gastric passage. A correlation between urease production and the presence of the *trh* and *trh/tdh* genes in strains of *V. parahaemolyticus* also was recently reported in Japan[129,156] and in Thailand;[155] however, these investigators observed a lesser correlation between the production of the enzyme and the presence of *tdh*. Nonetheless, a simple laboratory test for urease production may help to screen for the potentially pathogenic strains.

48.4.3 *V. vulnificus*

The mechanism(s) of development of primary septicemia attributed to *V. vulnificus* are not completely understood.[127] Both clinical and environmental strains produce an extracellular cytotoxin-hemolysin, the more virulent strains producing higher titers under laboratory conditions.[166,167] This cytolysin, of approximate molecular weight 56,000 daltons, is hemolytic to mammalian erythrocytes, cytotoxic to Chinese hamster ovary (CHO) cells, affects vascular permeability of Guinea pig skin, and is lethal to mice. Because all strains possess the cytotoxin-hemolysin gene and this is specific to *V. vulnificus*, a gene probe procedure has been used for detection and identification of this bacterium,[176,177] but not for virulence assessment.[44,64] Some strains of *V. vulnificus* are highly lethal to mice in several different bioassays. Others are considered avirulent, requiring a significantly greater number of cells to kill mice. Thus the cytotoxin-hemolysin may only play a small role in virulence. *V. vulnificus* produces a variety of extracellular products including protease, elastase, collagenase, lipase, phospholipase, mucinase, hyaluronidase, and fibrinolysin; however, these have not as yet been demonstrated to be involved in pathogenesis.[127]

The presence of a polysaccharide capsule appears to be essential for the infection process, most likely conferring resistance to phagocytosis. Encapsulated cells can be demonstrated on nonselective laboratory medium, appearing as opaque colonies, while acapsular cells yield translucent colonies.[148] On subculture, acapsular cells can be obtained from encapsulated cells but not the reverse. The encapsulated cells are significantly more virulent to mice than are the acapsular form, based on LD_{50} assessment; acapsular forms have been reported as avirulent. This difference is important in the laboratory when selecting isolates for additional study and virulence assessment. At least 10 capsular polysaccharide serotypes of *V. vulnificus* have been identified.[146] Clinical isolates associated with primary septicemia were represented in each of the 10 serotypes; however, only 45% of clinical isolates and only 8% of environmental isolates were typable. The epidemiological value of this serotyping scheme is yet to be determined. Also to be determined is the extent to which encapsulated and acapsular forms exist in the environment and whether certain environmental conditions select for either form. Several studies have reported that environmental isolates are as virulent to mice as clinical strains, and highly virulent strains are frequently encountered in environmental samples.[86,152,166]

Five serological varieties of LPS of *V. vulnificus* have been identified,[146] but the chemical composition of only one LPS has been reported. The relative virulence of strains in each of these serotypes has yet to be determined. A partially purified LPS extracted from a strain on intravenous injection into rats caused rapid onset of hypotension, followed by decreased heart rate and death within 30 to 60 minutes.[111] Hypotension, along with fever, tissue destruction, and hemorrhagia, are classical symptoms of Gram-negative endotoxic shock. All of these symptoms are manifested in the primary septicemia caused by *V. vulnificus.* An LPS-induced enzyme, nitric oxide synthase, responsible for the release of nitric oxide and resultant tissue destruction, has been suggested as the cause of the toxic shock syndrome observed following infection by this pathogen.

Iron plays an important role in the pathogenesis of *V. vulnificus.* Using an iron-overloaded mouse assay, LD_{50} values of strains were reduced significantly compared with those of the same strain tested in untreated mice.[152,178] This response to serum iron coincides with the epidemiological findings that severe infections occur predominantly in individuals with elevated serum iron levels. Normal human serum inhibited the growth of *V. vulnificus* because the organism could not compete for transferrin-bound iron;[147] however, when transferrin was saturated with iron, virulent strains were able to compete for the iron and multiply. Virulent strains were also able to grow when two other iron-binding proteins, lactoferrin and ferritin, were iron-saturated. Only the virulent, encapsulated strains were able to grow. Two siderophores are produced by *V. vulnificus,* uncommon for *Vibrio* species, but their role in pathogenesis is undetermined.[127] *V. vulnificus* is able to overcome the binding of free hemoglobin by the serum protein haptoglobin and acquire heme iron. An extracellular protease contributes to the efficient utilization of heme by this organism.[125]

48.4.4 Other *Vibrio* spp.

Of the other *Vibrio* species involved in human illnesses, little is known regarding their possible virulence mechanisms.[72] Other than those mentioned above, potential virulence factors for these less common pathogens include heat-stable and -labile enterotoxins (*V. fluvialis, V. furnissii, V. hollisae*), cytolysins (*V. fluvialis, V. metschnikovii, V. damsela*), cytotoxin (*V. fluvialis*), thermostable direct hemolysin (*V. hollisae, V. mimicus*), and the enzymes collagenase (*V. alginolyticus*), protease (*V. mimicus*), and mucinase (non-O1 *V. cholerae, V. mimicus, V. fluvialis*). A cholera-like toxin essentially identical to CT was reportedly produced by two diarrhea-related strains of *V. mimicus.*[151]

48.5 INCIDENCE IN THE ENVIRONMENT AND FOOD

Vibrios are naturally occurring environmental bacteria, present in virtually all coastal waters of tropical and temperate regions of the world. Of the bacterial species encountered in this environment, the majority are vibrios. Coastal areas with brackish waters and estuarine regions are niches for many species, including strains of toxigenic O1 *V. cholerae.* Epidemic cholera strains are endemic in several regions including Australia and the US Gulf Coast, and are occasionally involved in illnesses in those regions. *V. cholerae* O1 strains are occasionally encountered in the environment in nonendemic areas, but they are normally nontoxigenic and considered to be nonpathogenic.[77] Ecological studies of *V. cholerae,*[78] *V. parahaemolyticus,*[76] *V. vulnificus,*[127,175] and *V. mimicus*[25] identified the physical factors that enhanced their incidence and distribution in the environment.

Water salinity is an important physical parameter in the ecology of these organisms. Several of the pathogenic species are more prevalent and found in higher numbers in areas where water has a general salinity range of 2 to 25 parts per thousand (ppt). The lower salinity range of 2 to 5 ppt, in areas with significant fresh water inclusion, favors *V. cholerae, V. mimicus,* and *V. vulnificus.* These three species are less prevalent or rarely recovered in water of salinity 30 ppt or greater found in the open ocean. *V. vulnificus* levels decreased by 58% and 88%, respectively, in water of salinities of 30 and 35 ppt.[79] Water samples of lower salinity and those collected closer to the bottom had increased concentrations of *V. vulnificus.*[175] Many estuarine areas fluctuate in salinity due to the amount of rainfall, to fresh water inclusion from streams or rivers, and to tidal action, which will also influence the incidence of these species.

Pathogenic species of *Vibrio* are seldom isolated from water at a temperature below 10° C but are more frequently isolated from water between 15° C and 35° C. During colder months, recoveries of some of these pathogens can be made only from sediment, where they may be insulated from the lower temperatures. *V. vulnificus* was not isolated from environmental samples when the water temperature was below 8° C; however, this organism was isolated from oysters when the temperature was 7.6° C.[175] The seasonal occurrence of vibrios in temperate regions is due to the effect of temperature changes and is correlated with the frequency of reports of infections. In regions where the water temperature is warmer year-round, this seasonality is not as dramatic.

The environmental presence of pathogenic vibrios does not distinctly correlate with the presence of human sewage, although the presence of sewage may add nutrients to the water that would enhance survival of many of these species. It is unlikely that a monitoring program that uses indicators of fecal pollution, such as *Escherichia coli*, would be effective in an area that is not subject to sewage pollution in indicating the presence of vibrio pathogens and the potential vibrio hazard in seafood, such as mollusks. Endemic *V. cholerae* strains, however, are more prevalent in regions where epidemics have occurred and there is an inclusion of human waste into the aquatic environment; thus, a monitoring program may identify potentially hazardous seafood gathered from those areas.

A relationship exists between several *Vibrio* species and the phytoplankton and zooplankton in the water. Vibrios are chitinoclastic and their ability to digest chitin may play a role in their persistence in the sediment. *V. cholerae, V. parahaemolyticus,* and *V. vulnificus* are able to colonize copepods and crustacea due to the presence of chitin. It is suggested that attachment to planktonic forms enhances survival during adverse environmental conditions. *V. cholerae* also colonizes other aquatic biota such as water hyacinths in Bangladesh, seemingly extending its persistence in freshwater environments.[77]

Due to the ability of vibrios to attach to material suspended in the water, the animals that frequent these environments can be expected to pick up these vibrios during feeding. No particular animal reservoir has been identified; however, pathogenic vibrios are commonly found on surfaces or in the intestinal contents of marine animals. Seafood harvested from coastal and inshore areas of many parts of the world has been reported frequently to contain pathogenic species. In several of these reports, however, it was not indicated whether pathogenic strains, such as the KP+ *V. parahaemolyticus,* were encountered. A number of these reports are incidence studies and the levels of pathogens found were not reported. Products included in these studies were several species of finfish, squid, crustacea (shrimp, crab, lobster), and mollusca (oysters, clams, cockles, mussels, conch). The incidence of *V. parahaemolyticus* during processing steps of two oyster shucking operations in the State of Washington has been studied.[83] Levels of *V. parahaemolyticus* were traced from the freshly harvested shellstock, shucked oysters, washed and packed oysters, through the retail shucked product in jars. During a warm month of the year, 64% (91) of 142 total inplant samples collected contained *V. parahaemolyticus* with 20% of the 91 samples containing KP+ strains. Nearly one half of the final product jars contained KP+ *V. parahaemolyticus*; however, levels were less than 100 g^{-1}. In most samples, the total *V. parahaemolyticus* population exceeded that of the KP+ strains present; for example, shucked oysters prior to the wash step contained 2100 *V. parahaemolyticus* g^{-1}, 720 g^{-1} of these being KP+ strains. During the spring when the water temperature was lower, only 15% of 117 samples contained *V. parahaemolyticus*. KP+ strains were not recovered during this period.

There have not been any extensive surveys for the presence of pathogenic vibrios in food other than seafood. Due to the halophilic nature of these organisms, they would not be expected in other environments. In one of the first incidence studies for the presence of *V. metschnikovii* in seafood, the organism was isolated from a wide variety of products at the retail market level, including 12 common species of finfish, clams, oysters, mussels, scallops, shrimp, and a surimi-based product.[23] This organism appears to be quite prevalent in seafood; this may be of public health significance, although *V. metschnikovii* rarely causes human illness. The reservoir for *V. cincinnatiensis* has not been identified and, to date, no incidence studies in seafood have been reported. The presence of *V. metschnikovii* and the other species that are frequently encountered in seafood at the market level obviously indicates that the proper refrigerated storage of seafood is essential to prevent multiplication of potentially pathogenic vibrios.

Nonmarine food has been examined during cholera epidemics to determine modes of transmission, but routine incidence studies are not warranted. Foods investigated in epidemic areas include rice, millet gruel, vegetables, and fruit (see below). Imported vegetables from South America were examined for the presence of *V. cholerae* by several countries from 1992 to 1994 after the epidemic in that region intensified. These monitoring programs were initiated to prevent the possible spread of the strain outside Latin America. Several Latin American countries temporarily lost their European market for produce, creating a significant economic impact for the exporting country. Frozen seafood imports from South and Central America were also examined during this period. In the US, more than 600 imported seafood samples were examined. *V. cholerae* O1 was not isolated from any of the samples; however, non-O1 *V. cholerae* was isolated from 27, suggesting a risk that the epidemic strain could be conveyed to other regions.

48.6 EPIDEMIOLOGY

48.6.1 *V. cholerae*

Water plays a critical role in the transmission of cholera. Snow, in the mid 1800s, determined this role in England during the second pandemic.[132] The "Broadstreet Pump," a central supply of public drinking water in London, became infamous. The drinking water was contaminated with the epidemic strain by sewage discharge into the Thames River. The many investigations of cholera since Snow's discovery have consistently identified water as a source of the organism causing rapid spread of disease during epidemics.[80,115] In countries of recorded epidemics, the lack of potable water sources was the fundamental reason for spread of the disease. The contaminated water system of Trujillo, Peru, the drinking of unboiled water, and drinking from a household water-storage container in which hands had been introduced were all highly associated with the spread of cholera in that country.[160] Household water supplies, ie, cisterns used for collection and storage, often become contaminated by family members when washing their hands. During the 1991 South American epidemic, ice made from contaminated water was also incriminated in the transmission.[136] In Portugal, contaminated spring water that was bottled and distributed was responsible for a cholera outbreak of more than 100 cases.[15]

Food also plays a major role in the spread of cholera.[80,115,134] It is sometimes difficult to determine whether the food became contaminated by direct environmental contact or by an infected food handler, or whether the water used in food preparation was contaminated. There is evidence that water contaminated by sewage was used during preparation of food in outbreaks in the US, involving workers on an off-shore oil platform,[74] and also in Peru from prepared rice.[136] In South America, vegetables irrigated with untreated sewage were associated with the spread of that epidemic.[160] A variety of foods have been implicated in transmission of cholera (Table 48–4). Seafood implicated includes oysters, clams, mussels, cockles, crustacea, squid, and raw, salted, or dried fish. Other foods include cooked rice and legumes, millet gruel, raw vegetables, fruit, and frozen coconut milk. Ceviche, a dish made with raw marinated fish, was suspected of transmission in South America, but this was not substantiated. Fish used in the preparation of ceviche were harvested from coastal waters contaminated with the epidemic strain. In Ecuador, eating raw seafood and cooked crab was associated with the transmission of cholera, along with drinking unboiled water and a beverage from a street vendor.[173] Food obtained from street vendors was highly incriminated in the South American epidemic[164] and also in other countries during earlier epidemics.[102] In the US, the major domestic food vehicle for cholera in the past 25 years was crab meat.[172]

Illness caused by serogroups of *V. cholerae* other than O1 and O139 has most commonly been associated with the consumption of raw oysters in the US.[119] Outbreaks in other countries have been linked to the consumption of contaminated meat, vegetables, chopped eggs, potatoes, and gelatin.

48.6.2 Other *Vibrio* spp.

Illness due to *Vibrio* spp. other than O1 and O139 *V. cholerae* is consistently associated with a recent history of consumption of seafood. Many of the infections occur seasonally, in the warm months of the year, correlating with the increased occurrence of these species in the marine environment. Epidemiological evidence of seafood as a vector is lacking in some infections. Consumption of raw oysters is highly incriminated in epidemiological investigations of illness caused by most vibrios.[72,119,137] Indeed, the primary septicemia caused by *V. vulnificus* has been associated clearly with raw oyster consumption in more than 85% of cases.[127] The filter-feeding oyster can concentrate the bacteria present in the growing waters. High levels of the pathogenic vibrios have been reported seasonally in some of numerous incidence studies and this correlates with seasonal occurrence of most of the illnesses. Clams, cockles, and mussels also have been incriminated, but these mollusca are less often consumed raw than are oysters. In the US, consumption of molluscan shellfish accounts for the majority of gastroenteritis cases from seafood,[137] and *V. parahaemolyticus* appears to be the most common bacterial pathogen associated with shellfish consumption. Many of the documented cases involve a single incidence of illness and thus are not recorded as an outbreak, which requires two or more cases.[137] In a 2-year study of illnesses associated with raw oyster consumption in Florida, the reported disease agents in decreasing order of frequency were *V. parahaemolyticus*, non-O1 *V. cholerae*, *V. vulnificus*, *V. hollisae*, *V. mimicus*, *V. fluvialis*, and O1 *V. cholerae*.[89] Similar findings

Year	*Place*	*Number of Cases*	*Source*	*Reference*
1961	Philippines	330	Raw shrimp	75
1973	Italy	278	Raw seafood	5
1974	Portugal	2,467	Raw/undercooked cockles	14
1974	Portugal	136	Bottled water	15
1977	Louisiana (US)	11	Boiled/steamed shrimp	18
1978	Gilbert Islands	572	Raw clams, sardines	108
1981	Texas (US)	15	Cooked rice	74
1982	Singapore	37	Seafood	56
1987	Thailand	24	Uncooked pork	158
1988	Thailand	71	Uncooked beef	157
1991	Maryland (US)	3	Frozen coconut milk	165

were also reported for infections reported in one year in four Gulf Coast states.[100]

During the mid 1970s, oyster harvesting during summer months along the Gulf Coast region of the US was initiated due to the demand for the product. During this period, infections were recorded that eventually were attributed to *V. vulnificus*. During summer months, levels of *V. vulnificus* in oysters harvested from the Gulf of Mexico have been found to exceed 1 million g^{-1}.[162] These oysters are shipped to other areas of the US and large numbers are consumed raw. In most instances an individual consumes between 6 and 12 oysters or more; thus the number of *V. vulnificus* ingested at one time can be quite substantial. This suggests that several million of these organisms are consumed in raw oysters by some individuals without resultant illness. The attack rate, then, is seemingly quite low considering the estimated number of individuals that consume raw oysters. From 1981 through 1992, 72 *V. vulnificus* infections were reported in Florida, and this organism is the leading reported cause of death from foodborne illness in that state.[67] Eighteen cases of *V. vulnificus* septicemia have been reported for a 6-year period in Taiwan.[26] This bacterium infected two individuals with alcoholic cirrhosis in Thailand[174] and was reported as the cause of infection of four individuals in Korea in a 2-year period.[88]

In Japan, the high incidence of *V. parahaemolyticus* gastroenteritis results from the national custom of raw fish consumption. For a 10-year period (1963 to 1972), there were 300 to 500 outbreaks and 5,000 to 14,000 cases of illness due to *V. parahaemolyticus* yearly in that country.[126] In contrast, the large outbreaks of *V. parahaemolyticus* gastroenteritis in the US have been traced to cooked shrimp or crab that was contaminated after cooking at seafood processors. This may be due to a much lower frequency of raw fish consumption in the US than in Japan. In 1971, in Maryland, an estimated 320-case outbreak occurred from steamed crab,[117] and an outbreak involving an estimated 600 cases occurred in Louisiana from consumption of contaminated boiled shrimp.[6] Fresh shrimp, improperly stored, used in a salad served by a restaurant, caused acute gastrointestinal illness in 40 people in Panama.[93] Many of the US epidemiological reports regarding illness due to this organism have common factors involved; these include inadequate refrigeration (improper storage temperature, 75%), inadequate cooking (92%), and recontamination after cooking of the product (75%).[9]

It was estimated from a risk assessment study by the US Food and Drug Administration (FDA) and the Centers for Disease Control and Prevention that the chance of contracting molluscan shellfishborne illness from all causes in the US was 1 for every 1,000 to 2,000 servings consumed raw; whereas the overall chance of seafoodborne illness was 1 in 250,000 servings.[114] Excluding raw shellfish consumption, accounting for approximately 85% of the seafoodborne illnesses, the chance of illness was estimated at 1 in 1 million servings. Thus, the elimination of raw shellfish from the diet would substantially reduce the number of seafoodborne infections and simply cooking all shellfish would drastically reduce the risk and the number of illnesses. Even so, the risk of illness from seafood consumption, including raw shellfish consumption, was estimated to be at least 10 times safer than for eating chicken in the US, estimated as 1 illness in 25,000 servings.

Increased travel and the transport of food products between countries has increased the potential for transmission of these organisms, as is shown by incidents such as the outbreak of cholera from imported coconut milk.[165] Cruise ships have been involved in several large outbreaks of *V. parahaemolyticus* gastroenteritis,[168] and food served on airlines has been implicated in cholera infections.[24,172] Travelers returning from countries with current epidemics or areas of endemic cholera have become infected from food consumed prior to departure or served on the airplane. In a few instances, travelers transported contaminated products in their baggage to another country. Cargo ships may have been responsible for transmitting the Latin American epidemic cholera strain to another country's coastal waters[35] via contaminated bilge water.[106]

Molecular subtyping techniques have very recently shown their value in identifying outbreak strains for epidemiological purposes. This is very evident in the results of subtyping epidemic strains of *V. cholerae* from Latin America and tracing the spread of the organism.[169] A standardized ribotyping scheme, based on restriction fragment length polymorphism (RFLP) patterns, has been proposed for *V. cholerae* O1 so that intralaboratory results are comparable.[133] PCR amplification of the CT gene was valuable also in detecting the epidemic strain in contaminated samples during epidemiological investigations.[50] Recently, the application of pulsed field gel electrophoresis (PFGE) has proven to be a very discriminating way to measure the RFLP of *V. cholerae*. Multilocus enzyme electrophoresis (MEE) is a useful epidemic marker system and also a way to measure the relatedness of *V. cholerae* strains.[169] These techniques identified two distinct strains of toxigenic *V. cholerae* O1 currently epidemic in Latin America.[46] The specifics of these techniques are discussed in Chapter 64. These techniques may soon be applied to other pathogenic *Vibrio* species to improve epidemiological investigations.

48.7 FACTORS AFFECTING SURVIVAL AND GROWTH

48.7.1 Temperature

Vibrios are mesophilic organisms; thus they thrive in the temperature range of 15° C to 40° C. No growth of *V. parahaemolyticus* was obtained at 10° C or 46° C.[4] The ability of some of these species to grow at 43° C has allowed for a temperature-selective approach to isolation[38] and is also used for identification.[44,84] Optimum growth is at 37° C for most of the pathogenic species. Several species have generation times of less than 20 minutes in some food[71] and 16 minutes in laboratory medium with 2.9% NaCl.[10] Although some strains may grow at 10° C or at slightly lower temperatures, they do not grow at refrigeration temperatures of 4° C or lower. Consequently, storage of seafood at recommended refrigeration temperatures (less than 4.4° C) immediately after harvest is essential to prevent an increase in numbers of vibrios. Generally, a slow decline in numbers is reported during extended storage. For example, for shellstock oysters in refrigerated storage, a steady decline of approximately a 4 $\log_{10}$ reduction was observed over 3 weeks for *V. parahaemolyticus* and over 2 weeks for *V. vulnificus*.[131] Postharvest storage at 10° C of oyster shellstock prevented multiplication of vibrios.[29] *V. parahaemolyticus* was recovered after 48 days from presterilized fish homogenate inoculated at approximately 10^7 g^{-1} and stored at 0.6° C, with a $\log_{10}$ reduction value of 3.8 for one strain.[105] It appears, then, that a refrigerated seafood may retain vibrios at a level that may cause illness for the approximate shelf-life of the product, at which time it would likely become unacceptable for consumption due to the natural bacterial and autolytic decomposition.

Freezing generally causes a reduction in levels of vibrios during storage, by 3 to 4 $\log_{10}$ units or greater. Recoveries after storage for 8 days at –20° C have been reported for *V. parahaemolyticus* in seafood,[168] after 3 months in rock lobster tails inoculated at 10^4 to 10^6 per sample and stored at –18° C,[94] and both *V. parahaemolyticus* and *V. vulnificus* were recovered from presterilized shrimp homogenate inoculated at approximately 10^8 g^{-1}, after 40 days' storage at –20° C and after 30 days at 4° C with about a 6 $\log_{10}$ reduction.[16] *V. vulnificus* was recovered after 10 weeks in naturally contaminated, frozen (–20° C), shucked oysters with an approximate 4 $\log_{10}$ reduction,[131] but only a 1.5 $\log_{10}$ reduction after 14 days at 3° C was observed in shellstock oysters allowed to naturally uptake *V. vulnificus* from inoculated seawater to about10^5 g^{-1}.[85] Significantly lower levels (4 $\log_{10}$ reduction) of *V. vulnificus* were recovered from vacuum-packaged oysters, inoculated at approximately 10^5 g^{-1}, after 70 days at –20° C than normally packaged oysters.[131] After inoculation at levels of 10^6 to 10^7 g^{-1} into shrimp, crab, and oyster homogenates, which were then stored at 7° C and –20° C for 21 days, the numbers of viable *V. cholerae* O1 were reduced between 10^3- and 10^5-fold.[135] Survival probably depends more on the freeze-thaw cycle and the protection offered by the food than the actual storage temperature. An increase in the NaCl concentration to a range of 3% to 12% (w/v) reportedly enhanced the tolerance of *V. parahaemolyticus* to cold temperature[30] and heat. The $D_{47°C}$ values in aqueous solutions of 0.5%, and 7.5% w/v NaCl were 0.8 and 6.5 minutes respectively.[12] Cells grown at increased temperature (21° C, 29° C, and 37° C) in broth containing increased concentrations of NaCl (0.5%, 3.0%, and 7.5%) showed greater heat resistance in a buffer containing the higher concentrations of NaCl.[12]

Other studies have shown that ambient-temperature storage of cooked shrimp, crab, octopus, and oyster shellstock promoted rapid growth of *V. parahaemolyticus* and that unchilled, oyster shellstock supported the growth of naturally occurring vibrios, including pathogenic species.[127,168] *V. cholerae* O1 strains rapidly increased by 3 to 6 $\log_{10}$ in 24 to 32 hours in cooked foods, such as rice, lentils, eggs, and raw vegetables even at 22° C.[92]

Vibrios are susceptible to heat, and mild heating of seafood reduces their numbers. Boiling rapidly destroys vibrios, and an internal temperature of 60° C for several minutes appears to be sufficient to eliminate the pathogenic strains, eg, causing a 10^4- to 10^5-fold reduction of *V. cholerae*.[17] Table 48–5 lists *D* values in minutes for three species in different suspending media. In rice and fish, a 10-min treatment at 60° C eliminated 10^4 to 10^5 *V. cholerae*[59] and a 30-second immersion of fruits and vegetables in boiling water killed the organism.[49] A pasteurization temperature of 57.2° C for 30 minutes reduced *V. cholerae* levels 4 to 5 $\log_{10}$ in shucked oysters.[17] *V. parahaemolyticus* was found to be highly susceptible to less than 2 minutes of microwave heating at 800 w.[62] Oysters naturally contaminated with *V. vulnificus* at a level of 6×10^4 g^{-1} were heated at 50° C for 10 min, resulting in a reduction in numbers of *V. vulnificus* to <0.3 most probable number (MPN) g^{-1}, the minimum detection level.[28]

48.7.2 Moisture and pH

Foods with a high moisture content allow the survival of *Vibrio* spp. The a_w value must be greater than 0.93. The minimum a_w, controlled by glycerol, for *V. parahaemolyticus* growth was reported as 0.937 and as 0.945 controlled by NaCl, incubated 20 days at 29° C.[10] In addition to the water content of a food, the surface humidity of a stored dried or semidried product is also an important factor.

Survival is better in foods of neutral or near neutral pH, such as seafood, than in foods with a pH of 5 or lower.[141] *V. cholerae* survived only 1 day at pH 5 but up to 3 weeks at pH 8 and 10 at room temperature in cooked eggplant inoculated at 2×10^4 g^{-1},[49] and no growth occurred in food with a pH lower than 5.5.[141] *V. cholerae* multiplied rapidly in peanut sauce (pH 6.0) but not in a tomato-based sauce (pH 5.0).[153] Acidic sauces used in preparation of certain seafood dishes[115] can restrict vibrio growth if in contact with the organism; however, there is unlikely to be much effect on the internal vibrios that would be present in filter-feeding shellfish. A pH of 4.8 adjusted with HCl was the minimum reported for growth of *V. parahaemolyticus* in tryptic soy broth with a total concentration of 3% (w/v) NaCl.[11] Proteinaceous food with a pH above 5.8 supported growth of *V. parahaemolyticus* even at 9° C, but not beans with a pH of 4.95.[122] Seafood cocktail sauce (pH 3.3 to 3.4) added to shrimp in a 2 to 1 ratio accelerated die-off of *V. parahaemolyticus*.[19] Seafoods are high in protein, contain the nutrients necessary for growth of vibrios, and thus must be considered highly perishable and handled as such.

48.7.3 Antimicrobials, Disinfectants, and Preservatives

Nine species of vibrio from more than 200 clinical and environmental sources tested for antimicrobial susceptibilities were reported to be resistant to sulphamethoxazole, trimethoprim, and the penicillins;[54] however, most were susceptible to tetracycline, chloramphenicol, the aminoglycosides, the quinolones, and the newer cephalosporins. Tetracycline is the antimicrobial of choice for the treatment of cholera,[77] *V. parahaemolyticus* infections,[168] and *V. vulnificus* septicemia and wound infections.[127]

Chlorine (100 ppm), a quaternary ammonium compound (50 ppm), and iodine (25 ppm) produced 6 $\log_{10}$ reductions of *V. cholerae* O1 strains suspended in phosphate buffered saline after exposure for 2 min.[107] The addition of 50 ppm chlorine to the washwater used in oyster processing failed to reduce the numbers of *V. cholerae* in the blower/washer within 5 to 10 minutes,[121] but chlorine and an iodophor tested separately at a concentration of 25 ppm reduced the numbers of *V. parahaemolyticus* by a factor of 10- to 100-fold during oyster processing.[57] The iodophor was reported to be more effective than chlorine at 0° C and did not affect the sensory or visual appearance of the oysters. The effect of these disinfectants will depend on the concentration in the washwater of protein and other compounds that will complex with the antibacterials and inactivate them.

Diacetyl at a concentration of 0.05% was reported to be an effective antimicrobial against *V. vulnificus*

Table 48–5 *D* Values (min) Reported for *Vibrio* Species*

	V. cholerae	V. parahaemolyticus	V. vulnificus
$D_{47^\circ C}$			2.40 (PBS-2% w/v NaCl)[28] 1.30 (oysters)[17]
$D_{49^\circ C}$	1.70 (1% w/v peptone)[145] 8.15 (crab)[145] 9.17 (shrimp)[66]	0.82 (clam)[34]

in oysters stored at 5° C;[154] however, lactic acid and butylated hydroxyanisole (BHA) in concentrations up to 0.05% were found to be ineffective under the same conditions.

48.7.4 Viable but Nonculturable Cells

Although toxigenic *V. cholerae* was reported to survive for up to 70 days in sea salt solution at 25° C,[113] *V. cholerae, V. vulnificus,* and several other Gram-negative bacteria have been reported to survive in a viable but nonculturable state (VBNC) (Chapter 15).[128] This phenomenon occurs when bacterial cells retain metabolic function but are not culturable on routinely employed nonselective bacteriologic media. This dormant state is induced by extended exposure to saline water and nutrient deprivation. Cells become ovoid and reduced in size (ie, the starvation response). The VBNC state has been induced in the laboratory by inoculation into solutions containing between 0.5% and 2.5% (w/v) NaCl and storage at 5° C. Detection of VBNC cells by epifluorescent microscopy is detailed in Chapter 15. Cells transform into a normal size and culturable state when environmental conditions such as temperature and presence of nutrients become favorable. In the VBNC state, cells retain virulence characteristics. VBNC cells of *V. cholerae* induced fluid accumulation on injection into ligated rabbit ileal loops, and VBNC cells of *V. vulnificus* were lethal to adult mice. The VBNC state is a plausible explanation for the persistence, undetected, of these pathogens in the environment during adverse conditions, such as the colder winter water temperatures in temperate regions. In addition, this dormant state may explain, at least in part, why endemic cholera strains cannot be recovered from the environment for periods of time, only to re-emerge and once again infect humans.

48.8 PRINCIPLES OF DETECTION IN FOOD

48.8.1 Enrichment Procedures

Media devised for the detection of pathogenic vibrios in food and water capitalize on the ability of these organisms to grow rapidly at an alkaline pH, resist the inhibitory effects of bile salts and sodium tellurite, and tolerate salt. The addition of 1% (w/v) NaCl to a medium lacking salt is required for vibrio growth, while a final concentration of 2% to 3% is normally used for the halophilic species.[44,84] The optimal NaCl concentration for *V. cholerae* was reported as 2% (w/v)[113] and 3% (w/v) for *V. parahaemolyticus*.[168] Nonselective enrichment broths have been used prior to the use of a selective agar to detect low levels of vibrios in food and to resuscitate stressed cells that can occur from certain processing steps, ie, drying, heating, freezing.

Vibrios tolerate moderately alkaline conditions; thus enrichment media have been formulated with the final pH between 7 and 9. The medium widely used for detection and enumeration in food or water is alkaline peptone water (APW) consisting of 1% (w/v) peptone and 1% NaCl with a pH adjustment to 8.4 to 8.6.[44,84] The sample, usually 25 g or 50 g, is added to 225 ml or 450 ml of broth. Incubation is at 35° C to 37° C for 16 to 18 hours. Other enrichment broths include gelatin-phosphate-salt and Monsur's tellurite-bile salts broths for *V. cholerae*[84,140] and salt-polymyxin broth and glucose-salt-Teepol (GSTB) broth for *V. parahaemolyticus.*[168] Teepol, a surfactant, is no longer commercially available, however. APW has been the choice of many laboratories, including the FDA,[44] for enrichment of *Vibrio.* APW was the recommended enrichment for *V. parahaemolyticus*[41] and was significantly more effective than salt-polymyxin broth for recovery of *V. parahaemolyticus* and *V. vulnificus* and cold-stressed cells from seafood.[60]

Vibrios tend to multiply more rapidly than other microflora that may be present and that interfere with isolation, and at 35° C to 37° C incubation times of 16 to 18 hours are recommended. It is recommended that the enrichment broth be incubated for only 6 to 8 hours for *V. cholerae* isolation.[44] For food that may have been frozen, dried, or subjected to heat, enrichment broths should be incubated after the 6 to 8 hours incubation for an additional overnight period to resuscitate stressed cells.[44] The optimum enrichment incubation time for *V. parahaemolyticus* in APW was reported as 8 hours at 35° C.[42] A duplicate enrichment of sample in APW incubated at 42° C also is recommended for isolation of *V. cholerae,* at least from shellfish samples, in addition to one portion of sample enriched at 35° C.[38,44] This elevated temperature method, which was adopted as first action by the Association of Official Analytical Chemists (AOAC) International,[37] takes advantage of the inhibition of growth at this temperature of many of the naturally occurring bacteria present.

48.8.2 Isolation Procedures

After incubation, the enrichment broth is then streaked to a selective or differential agar medium. The most commonly used is TCBS,[44,77,84,168] which is available commercially. This selective and differential medium was designed originally for detection of *V. cholerae,*[90] but has also been effective for isolating the other pathogenic strains. This medium will differentiate the sucrose-fermentative species such as *V. cholerae, V. alginolyticus, V. fluvialis,* and *V. furnissii* from the sucrose nonfermenting species, *V. parahaemolyticus, V. vulnificus,* and *V. mimicus.* TCBS is the recommended selective agar to be used in conjunction with another selective agar for vibrios.[41] Other selective agars that have been used successfully include Monsur's taurocholate-tellurite-gelatin agar, polymyxin-mannose-tellurite agar, and Vibrio agar for *V. cholerae;*[77,140] and bromthymol blue-sucrose-Teepol agar, salt-starch agar, and several others for *V. parahaemolyticus.*[168] We have used successfully both TCBS and cellobiose-polymyxin-colistin agar (CPC)[103] with a slight modification[44] for the isolation of *V. vulnificus* from seafood.[85] *V. vulnificus* is phenotypically similar to *V. parahaemolyticus* on TCBS agar, and the modified CPC agar enhances differentiation of these two species based on cellobiose fermentation; most *V. parahaemolyticus* strains will not grow on modified CPC. The combination of APW enrichment and CPC agar was reported as more efficient for recovery of *V. vulnificus* than other broth and agar combinations[149] and than by a direct plating of sample to a selective agar.[85]

48.8.3 Identification

Once isolates are obtained, determination of oxidase activity is of primary importance to distinguish presumptive vibrios. The laboratory procedures for biochemical identification are quite straightforward, although it is necessary to supplement the media used for biochemical identification with NaCl. The pathogenic species have been well characterized and tables of distinguishing characteristics are published in several manuals[8,44,84,109] and presented in Table 48–3. The traditional biochemical procedures can be time consuming, taking up to 10 days to complete isolation, identification, and virulence assay. For more rapid identification, several commercial diagnostic kits are available, such as the API 20E (bioMérieux Vitek, Inc., Hazelwood, MO; Marcy l'Etoile, France) used for enteric organisms, and have been used successfully. It is recommended that the suspension of the test isolate be prepared in a 2% NaCl solution for identification of the halophilic species.[44] The API 20E was determined to be a valid identification system for the more commonly occurring members of the Vibrionaceae.[130] A gas chromatographic procedure for *V. vulnificus* using a capillary column to analyze fatty acid profiles has been adopted as first action by the AOAC International for identification of this species.[95]

Samples are usually tested for the presence or absence of *V. cholerae.* If it is isolated, serological testing for either serotypes O1 or O139 is of primary importance, indicating the presence of a potential pathogen. Antisera for O1 and O139 are available commercially. Generally, no serological determination is made for the other somatic groups and they are reported as non-O1, non-O139 *V. cholerae.* Isolates of O1 or O139 serotypes should be tested for the production of cholera toxin, since nontoxigenic O1 strains are occasionally encountered. The mere presence in a food or water of a toxigenic O1/O139 *V. cholerae* constitutes a public health hazard. Cholera toxin production can be detected by several means, including effect of culture filtrates on cells such as Y-1 mouse adrenal tumor or CHO, production of intestinal fluid accumulation in infant mice, or immunological procedures such as the commercial Oxoid "VET-RPLA" reverse passive latex agglutination diagnostic kit.[44] Several monoclonal antibody-based coagglutination procedures for the detection of *V. cholerae* O1 in water and stool samples have become available commercially.[77] This approach to detection is currently being evaluated for foods. In addition, test kits to detect the O139 serogroup may soon be available.

An enumeration procedure is used for both *V. parahaemolyticus* and *V. vulnificus* in seafood. This is based on the presumption that these species can be encountered frequently and not all strains encountered in seafood are pathogenic; however, this may only apply to *V. parahaemolyticus*. The infective dose of KP+ *V. parahaemolyticus* is thought to be 10^5 to 10^7 cells,[143] and most routine samples do not contain high levels of the pathogenic strains. Recently, a significant genomic diversity among *V. vulnificus* strains isolated from one oyster was reported[22] and it is unclear at present whether all these heterogeneous strains are virulent. One oyster could contain diverse strains differing in virulence. Thus it would be difficult to assess the significance of a sample containing *V. vulnificus* based merely on its presence because not all strains have been determined to be virulent and the infective dose has not been determined. The number of *V. vulnificus* per gram of sample may be more informative to assess the potential risk if the seafood is destined to be consumed raw.

An MPN technique is commonly used to enumerate these two species using an enrichment broth for resuscitation of stressed cells.[44,84] A series of dilutions of the sample is inoculated into the broth tubes. The MPN procedure allows for a detection level of from 2 to 3 organisms g^{-1} of sample depending on the number of tubes used in the MPN series. A three-tube multiple dilution procedure is recommended.[44] APW, the recommended enrichment, is incubated 16 to 18 hours at 35° C to 37° C. Turbid tubes are streaked to TCBS and modified CPC. Isolates identified as *V. parahaemolyticus* should then be tested for TDH production on Wagatsuma agar because most strains encountered are considered nonpathogenic. Virulence of *V. vulnificus* isolates can be determined by animal bioassay using iron supplemented mice.[44] Results of analysis are reported as the most probable number of *V. vulnificus* or of KP+ *V. parahaemolyticus* g^{-1} of sample.

48.8.4 Other Procedures

Membrane filtration methods for enumeration of *V. parahaemolyticus* have been developed,[171] one using a hydrophobic gridded membrane, HGMF.[45] These offer an overnight incubation; thus, more rapid results than obtained by enrichment. The detection level would be 100 g^{-1} of sample. The HGMF procedure was more effective for enumeration than the membrane procedure of Watkins et al.[171] and GSTB enrichment procedure.[36] Large-volume water samples can be concentrated with a membrane filtration technique. Similarly, Moore swabs—cotton gauze suspended in water—have been used successfully to concentrate *V. cholerae* from water and sewage.[118] A direct plating procedure to enumerate *V. vulnificus* on a cellobiose-based agar was also reported.[112]

The advent of genetics-based identification methods for pathogenic vibrios offers the advantages in speed and specificity. Genetic probes are used for the detection of specific genes by colony hybridization.[64] These probes include sequences for the CT gene, *ctx*, of *V. cholerae* and the *tdh* gene of *V. parahaemolyticus* to determine potential virulence and the species-specific cytotoxin-hemolysin gene, *vvhA*, of *V. vulnificus* for identification. The probes are labeled with a radioisotope for detection of hybridization, which may limit their use in some laboratories. With the use of gene probes, *V. parahaemolyticus* could be differentiated from *V. vulnificus*, and both enumerated, using the HGMF procedure.[81] Recent advances in nonisotopic labels for DNA have led to a broader application of a hybridization procedure. An alkaline phosphatase-labeled probe for *V. vulnificus* could detect 20 cfu ml^{-1} in water and 100 g^{-1} in oysters using a direct plating technique on a nonselective agar,[176] a 4-day analysis. Gene probes for the *ctx* gene of *V. cholerae* can detect 10^4 cfu in samples.[77] Lee et al.[97] reported that 10^5 cfu g^{-1} of TDH+ *V. parahaemolyticus* was detectable in oysters within 3 days using a *tdh* gene probe. Currently, digoxigenin-labeled probes are being used for hybridizations. The sensitivity of some of these procedures needs to be enhanced to detect lower levels of these pathogens, particularly toxigenic *V. cholerae*.

PCR also offers rapid detection of pathogenic vibrios in food and water samples but, at present, does not allow enumeration. By amplification of DNA fragments by PCR, pathogens can be detected in approximately 24 hours, although specialized equipment is required. Procedures to detect toxigenic *V. cholerae*,[91] either KP+ *or TDH+ V. parahaemolyticus*,[96] and *V. vulnificus*[65] in food by PCR have been reported. The gene probe and PCR techniques are discussed in detail in Chapter 64.

48.9 CONTROL OF *VIBRIO* SPECIES

More than one control measure is necessary to prevent, or at least reduce, food- and waterborne vibrio infections. Control is basically accomplished through a procedure that eliminates or significantly reduces the chance that an individual will ingest an infectious dose. It is highly unlikely that vibrio illnesses will be eliminated completely because the major vehicle of transmission of most of these pathogens, seafood, is part of the diet of so many people of the world. Environmental reservoirs of pathogenic strains exist such that when environmental conditions favor their increased presence, seafood gathered from those areas will likely continue to cause illness. However, knowledge of the risk factors to the host, the mechanism of virulence of these pathogens and their ecology, and safe food handling can help to reduce the incidence of illness. One should assume that any seafood potentially presents a hazard for vibrio infections.

Seafood is highly perishable after harvesting; thus handling practices must prevent deterioration of the product and growth of *Vibrio* species. This would include temperature control at the initial point of harvest. The handling practices required are similar to those for other perishable food products and include refrigeration, heat treatment, separation of raw and processed products, and sanitation of contact surfaces and equipment. These practices apply to both a seafood-processing environment and the home. Commercial processors must adhere to strict sanitation and good manufacturing practices to ensure a safe product. Because seafood is exported by many countries, an outbreak can occur at a location far removed from the source. The adoption of, and adherence to, a hazard analysis critical control point program to ensure safety of fishery products by countries entering into trade agreements can eliminate some of the hazards.

Generally, the following handling practices apply to seafood as well as other perishable food during processing as well as in the home. Thoroughly cook seafood to destroy bacteria, then prevent cross-contamination of cooked seafood from raw product by separate handling of raw and cooked product. Use appropriate handwashing between handling of raw and cooked product. Keep raw and cooked product below 4.4° C before preparing and serving. Avoid eating raw or undercooked seafood.

Seafood is not always cooked thoroughly; for example, shellfish often are steamed for short periods of time until the shell opens. The cooking recommendation for live oysters in the shell is to boil 3 to 5 minutes after the shell opens or steam 4 to 9 minutes in a steamer already steaming.[52] Shucked oysters should be boiled for 3 minutes or until the edges curl, fried at least 3 minutes at 375° F (190.5° C), baked 10 minutes at 450° F (232° C), or broiled 3 minutes at least 3 inches (7.7 cm) from the heat source. After cooking, if seafood is not consumed immediately, it should be stored at temperatures below 4° C (40° F) or above 60° C (140° F) and protected from recontamination by vibrios. Large recorded outbreaks of gastroenteritis caused by *V. parahaemolyticus* were due to a cooked seafood that was contaminated by equipment that also was used to hold raw product.[9,168] Cooking of all seafood would require a change of certain cultural customs, as many recipes use raw product.

Individuals with liver or blood disorders and the other medical conditions mentioned in Section 48.4.3 should be strongly advised to eat only thoroughly cooked seafood. Elimination of raw oyster consumption would prevent many of the *V. vulnificus* infections as well as those caused by other species. Recently in the US, there has been an intensive effort to notify the individuals deemed at risk due to this pathogen. Information was sent to medical groups and distributed via consumer and trade publications. In two states, retail seafood outlets, including restaurants, are required to post a hazard statement regarding raw shellfish consumption.[114] This information deals mainly with the increased risk of infection by *V. vulnificus*; however, risk due to other species of *Vibrio* also is implied. In one state the retail posting reads, "Warning—raw oysters, raw clams, and raw mussels can cause serious illness in persons with liver, stomach, blood, or immune disorders."[114] It may be difficult to reach all these at-risk individuals and many may not be aware of a medical condition that predisposes them to infection. Recently, there has been a noticeable decline in the demand for raw oysters from the US Gulf region, and the educational program is seemingly somewhat responsible.

The environmental factors that result in the prevalence or increased levels of some of these vibrios in the water have been reported. A monitoring system based on water temperature and salinity might be used to identify the time of year in which the harvest of seafood from a particular area should be restricted.[162] An example is the US proposal to restrict the harvest of Gulf Coast oysters for raw consumption between April 1 and October 31 in an attempt to reduce *V. vulnificus* infections. Epidemiological data suggest that approximately 90% of these infections could be prevented by this harvest restriction.[53]

The practice of relaying molluscan shellfish to a clean water environment, used in many areas, and the process of commercial depuration using sterilized seawater has met with varying results for vibrio pathogens. Water temperature and salinity appear to affect the extent to which vibrios can be purged. Most of the studies indicate an extended time period is required to reduce vibrio levels. In clams, a 2 $\log_{10}$ decline in numbers of *V. vulnificus* was reported after 24 hours in ozonated, artificial seawater,[144] while in the Australian oyster, 9×10^5 g^{-1} *V. parahaemolyticus* could be reduced to 10^2 after one day and approximately 10^1 after two days in ultraviolet-treated seawater[150] and the incidence of *V. cholerae* in this species of oysters was reduced.[47] In one study of depuration in oysters, *V. vulnificus* shifted from the digestive tract to other tissues and was not purged from the animal.[163] At a water temperature exceeding 15° C, *V. vulnificus* was reported to increase in numbers in the oyster during "depuration." At least for some vibrios and some species of shellfish, these processes may offer little hope as control measures and also may not be economically feasible for shellfish harvested from certain regions.

The application of low dose gamma radiation (1.0 kGy) to seafood is another approach to reduce vibrios. Numbers of *V. vulnificus* were reduced by over 5 $\log_{10}$ in shellstock oysters with a low mortality rate to the animal;[87] a similar reduction occurred in the shucked product. During exposure to ^{60}Co, *V. parahaemolyticus* was the most radiation-sensitive of the foodborne pathogens studied with a D_{10} equaling 0.03–0.04 kGy[39] and 2.8 and 5.4 $\log_{10}$ reductions in crabmeat and fish homogenate with a dose rate of 5 krads min^{-1} (0.05 kGy) at 24° C.[104] Higher doses, 50 krad (0.5 kGy), reduced by 6 $\log_{10}$ the number of *V. cholerae* on frog legs.[142] The use of irradiation as a control measure may depend on economic feasibility and the acceptability by consumers of products treated by this method.

Control of cholera is a more formidable and costly task, but two measures can help to control the spread of disease or reduce the number of cases. Probably the most important measure is to protect potable or treated water, for example by utilization of a piping system or by ensuring limited access to the source of the water to reduce chance of contamination. Education of people in areas that are at risk to at least boil water prior to drinking or use for food preparation is also critical. Point-source chlorination of home water sources has been effective. In endemic areas, even modest improvements in food and water sanitation have resulted in fewer cases of infection. Disposal of human sewage so it cannot contaminate drinking water sources is the second important measure. In the Western Hemisphere, an estimated 80,000 metric tons of human feces is produced daily with only a small fraction being treated,[13] and cholera will probably become endemic in Latin America unless sewage treatment is implemented rapidly. Safer food-handling practices, safer food sources, and personal hygiene all can play a role in reducing transmission of cholera by both food vendors and by family household members. Adequate sanitation also requires uncontaminated water for cleaning and hygiene. Costs of community systems for potable water dispersal and for sewage disposal are most likely prohibitive in economically stressed countries. Development of an effective vaccine offers some hope in at least reducing the number of cases and the mortality due to this disease in regions where cholera is endemic. If O139 *V. cholerae* persists and spreads, a vaccine may have to be developed to include components of this serogroup; however, vaccines might be counterproductive if they decrease the motivation to improve sanitation.

48.10 CONCLUDING REMARKS

There are challenges ahead for public health officials to control vibrio infections. We have come a long way in identifying strains and virulence mechanisms of these organisms and recognizing the groups of people who are more susceptible to infection. The vibrio group contains species that are naturally occurring aquatic organisms. Humans are just an intermediate host, with some more susceptible to infections than others. For centuries, food derived from the sea has been a staple in diets of many populations. Vibrios will never be eliminated from their environment and as long as humans continue to consume seafood, illnesses will no doubt occur. The gastronomic delight, the oyster, is the cause for many of these illnesses, albeit unwittingly. Oysters fit the category of "you are what you eat." An understanding of the complete mechanisms of disease, the virulence factors involved, and their contribution to the disease process, obtaining a complete epidemiological picture of all vibrio illnesses, and conducting further research into vibrio ecology and possible new control measures are all ingredients needed in our attempt to reduce infections caused by vibrios and reduce the risk associated with seafood consumption.

49.1 INTRODUCTION

The genus *Yersinia* of the family *Enterobacteriaceae* includes three well-established pathogens (*Yersinia pestis*, *Yersinia pseudotuberculosis*, and *Yersinia enterocolitica*) and several non-pathogens.[122,166] *Y. pestis* was isolated by Alexandre Yersin in 1894.[273]

The most important *Yersinia* infection, plague, which is caused by *Y. pestis*, is one of the most ancient recognized human diseases. Although infections caused by *Y. pseudotuberculosis* and *Y. enterocolitica* have only been reported more recently, it is nevertheless likely that these infections also have occurred for many years. Disease due to *Y. pseudotuberculosis* (first described in 1884) has been recognized since the beginning of the 20th century, and *Y. enterocolitica* was first shown to be associated with human disease in 1939.[165]

The current interest in *Y. enterocolitica* started in 1958 following a number of epizootics among chinchillas and hares,[106,166] and after the establishment of a causal relationship with abscedizing lymphadenitis in man. The similarity between the human and animal isolates was established in 1963,[135] and in 1964 the species name *Y. enterocolitica* was proposed formally by Frederiksen.[73] During the past 30 years, the bacterium has been found with increasing frequency as a cause of human disease and from animals and inanimate sources.

Y. enterocolitica is an important cause of gastroenteritis in humans, especially in temperate countries.[166,267,268] The possible risk of reactive arthritis following infection with *Y. enterocolitica* has led to further attention being paid to this microbe.[35,166] In many instances, attempts to isolate *Y. enterocolitica* from foods implicated in cases of disease in humans have been unsuccessful. However, evidence from large outbreaks of yersiniosis in the United States (US), Canada, and Japan[58] and from epidemiological studies of sporadic cases[192,241] has shown that *Y. enterocolitica* is a foodborne pathogen, and that pork is implicated frequently as the source of infection.[106,147,169,192,241] An important property of the bacterium is its ability to multiply at temperatures near to 0° C and, therefore, in many chilled foods.

Due to the relative lack of information on *Y. pseudotuberculosis* as a foodborne pathogen,[217] this bacterium will be considered less extensively than *Y. enterocolitica*. *Yersinia pseudotuberculosis* mainly causes epizootic disease, especially in rodents, with necrotizing granulomatous disease of liver, spleen, and lymph nodes.[8,9] In humans it may cause acute abdominal disease, septicemia, arthritis, and erythema nodosum.[3,134]

49.2 TAXONOMY AND CHARACTERISTICS OF *YERSINIA* SPP.

The genus *Yersinia* was proposed in 1944 by Van Loghem[250] for bacteria that were related to the genus *Pasteurella* and that were pathogenic. Thal[244] drew attention to evidence relating *Yersinia* to the Enterobacteriaceae. A general numerical taxonomic study from 1958 placed *Yersinia* between *Klebsiella* and *Escherichia coli*.[225] The allocation of *Yersinia* to the Enterobacteria was further supported by Frederiksen in 1964.[73]

49.2.1 Differentiation of *Y. enterocolitica* from Other *Yersinia* spp.

A range of strains of *Yersinia* variants has been isolated from animals, water, and food.[106,120,149,166] Many of these bacteria have characteristics that deviate considerably from the typical pattern shown by *Y. enterocolitica* but that, nevertheless, show that the bacteria concerned can be classified as belonging to the genus *Yersinia*.[122,166] Such *Y. enterocolitica*-like bacteria have now been divided on a genetic basis into seven new species:[10,22,24,25,38,39,40,249,263] *Yersinia frederiksenii*, *Yersinia kristensenii*, *Yersinia intermedia*, *Yersinia aldovae*, *Yersinia rohdei*, *Yersinia mollaretii*, and *Yersinia bercovieri*.

The latter four species are not included as separate species in *Bergey's Manual of Systematic Bacteriology*.[23] For practical reasons, the common term "*Y. enterocolitica*-like bacteria" is applied to these seven species. The species name *Y. enterocolitica* is reserved for the most typical strains, and it is only within this species that pathogenic strains have been found. It is important therefore to be able to differentiate the seven new species from *Y. enterocolitica*. This can be achieved by applying nine biochemical tests as described in Table 49–1, the fermentation of rhamnose, melibiose, and sucrose being key characteristics. *Y. pseudotuberculosis* is also included in Table 49–1. A description of the characteristics of *Y. enterocolitica* is given in Table 49–2.

Y. enterocolitica is a Gram-negative, oxidase-negative, catalase-positive, nitrate reductase-positive, facultative, anaerobic rod (occasionally coccoid) 0.5 to 0.8 × 1-3 µm in size.[23] It does not form capsules or spores. It is nonmotile at 35° C to 37° C, but motile at 22° C to 25° C with relatively few peritrichous flagellae. Some human pathogenic strains of serovar O:3 are, however, nonmotile at both temperatures. In addition, the bacterium is urease-positive, H_2S-negative, ferments mannitol, and produces acid, but not gas, from glucose.

The genus *Yersinia* also includes two further species that will not be considered further here: *Y. pestis* and *Y. ruckeri*, which is a fish pathogen.

49.2.2 Biovars and Serovars of *Y. enterocolitica*

The bacteria that are classified currently as *Y. enterocolitica* do not constitute a homogeneous group. Within the species, there is a wide spectrum of biochemical variants.[22,122,166,233] Such variations form the basis for dividing *Y. enterocolitica* into biovars. A number of different biotyping schemes have been described;[38,122,233,257] however, in 1987 Wauters et al.[264] described a revised biotyping scheme (Table 49–3) that differentiates between pathogenic (biovars 1B, 2, 3, 4, 5) and nonpathogenic (only biovar 1A) variants. In this chapter, the term biovar has been used in accordance with the latest edition of *Bergey's Manual*.[23] The proposed biovar 6[264] is reclassified into two new species: *Y. bercovieri* and *Y. mollaretii* (Table 49–1).[263]

Bergan, Biochemical and Serological Characterization of *Yersinia Enterocolitica*, in *Methods in Microbiology*, Vol. 15, T. Bergan and J.R. Norris, eds., pp. 295–344, © 1984, Academic Press, Inc.

O- and H-antigens. *Y. enterocolitica* can be divided into serovars using O-antigens. So far, 76 different O-factors have been described in both *Y. enterocolitica* and *Y. enterocolitica*-like bacteria.[259,261] A few strains, however, cannot be typed by this system, and the number of described antigen factors is, therefore, likely to increase in the future. Fifty-four H-factors have been recognized [S. Aleksic, personal communication, 1995],[261] but H-antigen determination is carried out rarely and most studies are limited to the O-antigens. Most isolates of *Y. enterocolitica* possess H-antigens consisting of several subfactors. The H-antigens are monophasic and remain stable after repeated subculture and after storage as stab cultures.[7] The great variability in H-antigens allows differentiation of strains that cannot be distinguished by any of the other typing methods employed (Table 49–7). Even though the preparation and standardization of specific antisera are both time consuming and costly, H-antigen typing can be

a valuable supplement to O-antigen typing and biochemical characterization of *Y. enterocolitica* in epidemiological investigations.

Correlation between Biovars, Serovars, Ecology, and Pathogenicity. The relationships between the biovars, the O-antigens, and the ecology of *Y. enterocolitica* and related species are presented in Table 49–4.[260]

Biovar 1A includes a large number of serovars that are found in the environment, in food, and occasionally in the digestive tract of animals and humans. They do not possess virulence properties and are of little or no clinical significance for man.

Biovars 1B, 2, 3, 4, and 5 are potential pathogens for man and animals. They exhibit pathogenic properties and, when freshly isolated, usually harbor the virulence plasmid. Strains of biovar 1B belong to a small number of pathogenic serovars, the most frequent being O:8, O:21, O:13a, and O:13b, whereas O:4, O:18, and O:20 occur less frequently. They have been isolated mainly in the US and were therefore called "American strains." Since the beginning of the 1990s, a few strains have been isolated outside North America in Europe, Japan, India, and Chile.[260]

Biovar 2 includes only two serovars, O:9 and O:5,27, which are pathogenic for man. O:9 is important in Belgium, Holland, and France, while O:5,27 is quite common in the US.[162,166,267]

Biovar 3 includes serovar O:1,2,3, which has been isolated mainly from chinchilla and rodents and rarely from man.[106,166] There are also a few serovars O:5,27 in this biovar.[260] In the beginning of the 1990s, a Voges-Proskauer-negative variant of biovar 3, belonging to serovar O:3, was isolated in Japan and East Asia and has become a prominent bio-serovar pathogenic for man in these countries.[260,261]

Biovar 4 contains only one serovar, O:3, which is the main pathogenic serovar for man, distributed worldwide. It is also isolated regularly from healthy pigs.[53,66,106,178,219,257,258]

Biovar 5 is of no importance for humans. It includes serovar O:2,3, which is found in hares and some other animals.[106,139,142,166,224,260]

Although some antigenic factors are linked to pathogenic strains, for example O:3, O:9, O:8, serotyping alone cannot be used to indicate pathogenicity because these antigenic factors also occur in nonpathogenic species or biovars. For instance, factor O:3 is common in *Y. frederiksenii* and may also be encountered in other species and in biovar 1A of *Y. enterocolitica*. Factor O:8 occurs in biovar 1A and in *Y. bercovieri*, and factor O:9 in *Y. frederiksenii*. Hence, antigenic typing of the strains should always be performed after appropriate biochemical characterization.

49.2.3 Serovars of *Y. pseudotuberculosis*

So far, 15 different O-groups have been described and 5 H-antigens defined in *Y. pseudotuberculosis*[28] [S. Aleksic, personal communication, 1995].

Table 49–4 Correlation between Biovars, O-antigens, and Ecology of *Y. enterocolitica* and Related Species

49.3 FEATURES OF THE DISEASES CAUSED BY FOODBORNE *YERSINIA* SPP.

49.3.1 Clinical Symptoms of Infection with *Y. enterocolitica*

Gastroenteritis is by far the most common symptom of *Y. enterocolitica* infection (yersiniosis) in humans.[35,58,166,270] The clinical picture is usually one of a self-limiting diarrhea associated with mild fever and abdominal pain.[270] Nausea and vomiting occur, but less frequently. The portion of the gastrointestinal tract usually involved is the ileocecal region.[213] The colon also may be affected and the infection may simulate Crohn's disease, which has a different prognosis.[85,251] Occasionally the infection is limited to the right fossa iliaca in the form of terminal ileitis or mesenteric lymphadenitis, with symptoms that can be confused with those of acute appendicitis. In several studies of patients with the appendicitis-like syndrome, *Y. enterocolitica* has been found in up to 9% of patients.[3,17,115,157,185,194,212] Infections with serovars O:3 or O:9 are, in some patients, followed by reactive arthritis[2] [Chapter 55], which is most common in patients possessing the tissue type HLA-B27. Often, although not always, the patient has shown prior gastrointestinal symptoms. Other complications seen with *Y. enterocolitica* infection are reactive skin complaints, erythema nodosum being the most common. Many such patients have no history of prior gastrointestinal involvement. Septicemia due to *Y. enterocolitica* is seen almost exclusively in individuals with underlying disease,[35] while those with cirrhosis and disorders associated with excess iron are predisposed particularly to infection and increased mortality.

Clinical symptoms are influenced by the age of the patient.[35,270] Gastroenteritis dominates in children and young people, while various forms of reactive arthritis are most common in young adults, and most patients with skin manifestations are adult females.[270] In Scandinavia, there is a relatively high incidence of both reactive arthritis (10% to 30%)[266] and erythema nodosum (30%),[4] caused by serovars O:3 and O:9. These forms of the disease have been almost totally absent in the US, where O:8, historically, has been the most common cause of yersiniosis. This situation may change, however, as illness caused by serovar O:3 is on the increase in the US.[29]

Transient carriage and excretion of both pathogenic and nonpathogenic *Y. enterocolitica* may occur following exposure to the bacteria. High rates of asymptomatic carriage have been reported in connection with outbreaks,[238] although in surveys unrelated to outbreaks, *Y. enterocolitica* has been isolated from the stools of fewer than 1% of individuals.[185] In patients with *Y. enterocolitica* enteritis, the organism may be excreted in the stools for lengthy periods after symptoms have resolved. In a study of Norwegian patients, convalescent carriage of *Y. enterocolitica* O:3 was detected in the stools of 27 (47.4%) of 57 patients for a median period of 40 days (range 17 to 116 days).[191]

49.3.2 Clinical Symptoms of Infection with *Y. pseudotuberculosis*

The clinical manifestations of infection with *Y. pseudotuberculosis* may include enteritis, abdominal pain, lymphadenitis mesenterica, pseudoappendicitis, sepsis, reactive arthritis, and erythema nodosum.[3,8,9,134]

49.4 MECHANISMS OF PATHOGENICITY OF *Y. ENTEROCOLITICA*

49.4.1 Pathogenesis and Immunity

Human infection due to *Y. enterocolitica* is predominantly by the oral route. The minimal infectious dose required to cause disease is unknown. In one volunteer, ingestion of 3.5×10^9 organisms was sufficient to produce illness.[235] The incubation period is uncertain, but has been estimated as being between 2 and 11 days.[207,235]

Enteric infection leads to proliferation of *Y. enterocolitica* in the lumen of the bowel and in the lymphoid tissue of the intestine. Adherence to and penetration into the epithelial cells of the intestinal mucosa are essential factors in the pathogenesis of *Y. enterocolitica* infection.[32,57,161,199] Reactive arthritis and erythema nodosum appear to be delayed immunologic sequelae of the original intestinal infection.

In humans, infection with pathogenic strains of *Y. enterocolitica* stimulates development of specific antibodies. It is not known whether specific serum antibodies protect against reinfection with *Y. enterocolitica* organisms of the same or different serovars. The immunological response can be measured by a variety of techniques, including tube agglutination, indirect hemagglutination, enzyme-linked immunosorbent assay (ELISA), and solid-phase radioimmunoassay.[17] An indirect immunofluorescent-antibody assay has also been used;[48] however, ELISA is probably the most suitable and extensively applied method in the world today. Agglutinating antibodies appear soon after the onset of illness and persist for 2 to 6 months. Some serovars may be associated with illness without eliciting a detectable serological response.[3,247]

The serological diagnosis of *Y. enterocolitica* infection may be complicated by the existence of cross-reactions between *Y. enterocolitica*, most notably serovar O:9, and such organisms as *Y. pseudotuberculosis, Brucella, Vibrio, Salmonella, Proteus,* and *Escherichia coli.*[184,259,265] The interpretation may also be confounded by high prevalence of seropositive individuals in the healthy population. Of 813 Norwegian military recruits selected at random, 67 (8.2%) had antibodies against *Y. enterocolitica* O:3.[181] Patients with thyroiditis of an immunological etiology have an unexplained increased frequency of cross-reacting antibodies to *Y. enterocolitica.*[220] Detection of antibodies to plasmid-encoded proteins, *Yersinia* outer membrane proteins (Yops), by immunoblots, has been suggested as a highly specific means of demonstrating previous *Y. enterocolitica* infection.[104,231] Demonstration of specific circulating IgA to the Yops is indicative of recent or persistent infection and is correlated strongly with the presence of virulent *Y. enterocolitica* in the intestinal lymphatic tissue of patients with reactive arthritis.

49.4.2 *In Vitro* Indicators of Virulence

The Virulence Plasmid. Human pathogenic strains of *Y. enterocolitica* possess a special plasmid 40 to 50 megadaltons in size.[43,199] The presence of this plasmid is an essential, although not sufficient, prerequisite for the bacterium to be able to induce disease. Properties associated with the chromosome are also necessary for virulence. Corresponding plasmids are found in *Y. pseudotuberculosis* and *Y. pestis*, and there is thus a family of related virulence plasmids within the genus *Yersinia.*[199] The way in which the plasmid contributes to virulence has not been elucidated fully. The presence of this virulence plasmid has been associated with several properties, most of which are phenotypically expressed only at elevated growth temperatures of 35° C to 37° C.[199] The list of such plasmid-mediated and temperature-regulated properties includes: Ca^{++}-dependent growth,[83,198,200] production of V and W antigens,[198] spontaneous autoagglutination,[141,223] mannose-resistant hemagglutination,[127] serum resistance,[193,198] binding of Congo Red dye,[202] hydrophobicity,[140] mouse virulence,[179,193,209,218] and production of a number of proteins,[47,199,200] of which one is a true outer membrane protein (YadA, previously termed Yop1).[160] This true outer membrane protein forms a fibrillar matrix on the bacterial surface and mediates cellular attachment and entry.[32] It also confers resistance to the bactericidal effect of normal human serum and inhibition of the anti-invasive effect of interferon.

The mechanism of virulence is known to vary even between different serovars within *Y. enterocolitica*. Plasmid-containing strains of O:8, O:13a, O:13b, and O:21 are lethal to orally infected mice, whereas O:3, O:9, and O:5,27 are not.[179,193,209,218] These latter serovars, however, are capable of maintaining intestinal colonization for at least 1 week after orogastric challenge.[179]

The Chromosome. Elements encoded by the chromosome are also necessary for maximum virulence. The pathogenic yersiniae share at least two chromosomal loci, *inv* and *ail*, that play a role in their entry into eukaryotic cells.[161] The *inv* and *ail* gene products can be classified as adhesins because they mediate adherence to the eukaryotic surface. Unlike other previously characterized bacterial adhesins, they also mediate entry into a variety of mammalian cells.

49.4.3 Virulence Assays

Two of the above-mentioned characteristics, Ca^{++}-dependent growth and spontaneous autoagglutination, have been employed frequently as indicators of the pathogenic properties of the bacterium. These tests depend on the presence of the plasmid; however, the plasmid may be lost in the course of a prolonged isolation procedure. Other situations where loss of the plasmid may occur are cultivation on magnesium oxalate agar at 37° C[198] and extended storage at refrigeration temperatures.[26] A test for pyrazinamidase activity has been included in the new biotyping scheme of Wauters et al.[264] (Table 49–3). The test is simple, reproducible, and shows a striking correlation between potential pathogenicity and lack of pyrazinamidase activity, independent of the presence of the virulence plasmid. The reliability of this test has been documented following studies of more than 1,000 *Y. enterocolitica* isolates representing a broad range of serovars and different geographical origins.[117] Pyrazinamidase activity is commonly found in all environmental strains, which never harbor the virulence plasmid. There are a few exceptions in biovar 1A strains that lack pyrazinamidase activity. Furthermore, in *Y. kristensenii*, the reaction often is weak. Pathogenic strains, whether or not the plasmid is still present, show a negative reaction. Also the invasiveness in HeLa cells is encoded chromosomally.[218] Only pyrazinamidase-negative, pathogenic strains are invasive for HeLa cells,[218] although they do not multiply within the cells.[64]

49.4.4 Enterotoxin Production

Many strains of *Y. enterocolitica* and related species produce a heat-stable enterotoxin (YEST) when the bacteria are cultured at 20° C to 30° C.[119,173,195] Certain strains, especially within the species *Y. kristensenii*, are also able to produce YEST at 4° C and 37° C.[119,126,173] This property is regulated by chromosomal genes and is independent of the virulence plasmid.

The toxin of *Y. enterocolitica* resembles the heat-stable enterotoxin (ST) of *E. coli* in pH stability, activity in suckling mice and in the rabbit ileal loop,[37] and the stimulation of guanylate cyclase activity;[112] however, unlike the ST of *E. coli*, the YEST is found only in the methanol-soluble fraction.[252] The toxin is not inactivated by exposure to 121° C for 30 min or by storage at 4° C for at least 5 months.[37] It is also highly resistant to enzymatic degradation,[188] but sensitive to treatment with 2-mercaptoethanol.[252] Purification of YEST reveals a protein with a molecular weight of about 3,000, and a high degree of amino acid homology with *E. coli* ST.[240]

Although there is no evidence to support the involvement of YEST in the pathogenesis of *Y. enterocolitica* enteritis, the possibility still remains that enterotoxigenic strains may produce foodborne intoxication by means of preformed enterotoxins.[119,126] This assumption is based on the fact that YEST is able to resist gastric acidity as well as temperatures used in food processing and storage without losing activity.[37] The ability to produce YEST at room and refrigeration temperature may give the "environmental" yersiniae a new significance in food hygiene as potential agents of foodborne intoxication.

49.5 INCIDENCE IN THE ENVIRONMENT AND IN FOODS

49.5.1 Incidence of *Y. enterocolitica* in Animals

Food Animals. Healthy pigs often are carriers of strains of *Y. enterocolitica* that are pathogenic to humans, in particular strains of O:3/biovar 4 and O:9/biovar 2.[106,120,217] Healthy pigs have been found to be infected with *Y. enterocolitica* O:3 in frequencies up to 85%.[53,66,106,174,175,178,219,221,257,258] The organisms are present in the oral cavity, especially the tongue and tonsils, and in the intestine and feces. Workers in Japan reported that O:3 strains were isolated from 85% of oral swabs from 40 freshly slaughtered, healthy pigs and presented evidence that the organism colonized the pigs' tonsils.[221] In this study, 34 (24.3%) of 140 pigs were carriers of the organism in the cecum, with counts ranging from fewer than 300 to 110,000 *Y. enterocolitica* g^{-1} of cecal contents. Strains of O:3 have been found frequently on the surface of freshly slaughtered pig carcasses (in frequencies up to 63.3%).[13,175] This is probably the result of spread of the organism via feces and intestinal contents during slaughter and dressing operations. The association between yersiniosis in humans and the consumption of raw pork in Belgium[241] and the apparently rare incidence of the infection in Moslem countries,[212] where consumption of pork is restricted, point to pork as a source of infection with *Y. enterocolitica*.

Other pathogenic strains do not appear to be as closely associated with pigs and may have a different ecology. In western Canada, O:8 and O:5,27 strains have been found most commonly in humans, but only O:5,27 strains were found in the throats of slaughter-age pigs.[217] In the US, O:5,27 strains were isolated from the cecal contents and feces of 2 of 50 pigs at slaughter.[138] Serovar O:8/biovar 1B, until recently considered to be the most common human pathogenic strain of *Y. enterocolitica* in the US[190] and in western Canada,[248] has seldom been reported in pigs.

Serovar O:3 was isolated from the rectal contents in 2 (3.0%) of 66 lambs in New Zealand.[45]

Surveys in New Zealand have found deer to carry both O:5,27/biovar 2 and O:9/biovar 2 [S. Fenwick, personal communication, 1996]. Antibodies against serovar O:9 have been found in sera from cattle in Belgium.[265]

In Norway, Krogstad[139] demonstrated outbreaks of *Y. enterocolitica* infection in goat herds in which serovar O:2/biovar 5 was implicated. He also described a case in which an animal attendant was infected by the same serovar. Biovar 5 has been isolated also from goats in New Zealand.[142] Enteritis in sheep and goats resulting from infection of *Y. enterocolitica* O:2,3/biovar 5 is also seen in Australia.[224]

Other Animals. Pigs, dogs, cats, and rodents, such as rats, may also occasionally be fecal carriers of O:3 and O:9.[71,82,99,106] The relative intimate contact between man and pets suggests a potential reciprocal transmission, although such an epidemiological link has not been clearly confirmed.[181,192] However, cats may have some importance as vehicles of transmission of *Y. enterocolitica* O:3 in pig herds.[222] O:3 has been isolated from 1 (0.9%) of 117 crows in Japan, and O:9 from one (0.7%) of 156 Japanese serows.[131]

It has been suggested that rodents may be reservoirs of O:8 and O:21 strains in North America,[217] and evidence has been published that this is indeed the case in Japan.[99] Serovars O:8 and O:21 are related closely in many ways (ie, biochemical profile, H antigens, animal virulence). Serovar 21 ("O:Tacoma") has been isolated from wild rodent fleas in the western US.[203]

As is the case with human pathogenic variants, the animal pathogenic strains also belong to particular combinations of serovars and biovars.[106,166] Serovar O:1/biovar 3 was responsible for widespread outbreaks in chinchilla both in Europe and the US during 1958–1964.[106,166] During the same period, epizootics were observed among hares along the French-Belgium frontier caused by serovar O:2/biovar 5.[106,166]

49.5.2 Incidence of *Y. pseudotuberculosis* in Animals

Y. pseudotuberculosis mainly causes epizootic disease, especially in rodents, with necrotizing granulomatous lesions in liver, spleen, and lymph nodes, infections in animals often being fatal.[8,9] *Y. pseudotuberculosis* has been isolated from both wild and domestic mammals as well as birds.[8,9] Rodents kept as fur animals, laboratory animals, and zoo animals, and birds kept in zoos and bird shops and as farm animals or pets are infected frequently.[8] Yersiniosis in deer in New Zealand is caused by *Y. pseudotuberculosis*, the occurrence of the disease correlating well with periods of stress, especially the nutritional and climatic stresses associated with winter.[101]

49.5.3 *Y. enterocolitica* in Environmental Reservoirs and Water

Although a range of different serovars and biovars has been isolated from the environment (eg, soil and water),[118,120,121,166] most belong to biovar 1A, according to the revised biotyping scheme described by Wauters et al.[264] (Table 49–3). As regards the so-called *Y. enterocolitica*-like bacteria, which also are common in the same environments, no clinical significance is attributed to most of the strains within biovar 1A;[35,166] however, such environmental strains have occasionally caused disease in immunocompromised patients.[35,166]

Shallow wells in particular, and rivers and lakes, are susceptible to contamination by surface runoff from rain or snow melt. Such runoff may become fecally contaminated by wild or domestic animals or by leakage from septic tanks or open latrines in the surrounding areas. Water is a significant reservoir of *Y. enterocolitica*;[41,98,125,143,144,210] however, most isolates of *Y. enterocolitica* and *Y. enterocolitica*-like bacteria obtained from water are variants with no known pathogenic significance to man.

Evidence that water supplies can be a source of pathogenic *Y. enterocolitica* has been found in certain outbreaks associated with contamination from water sources, and in a few sporadic cases, as well as case-control studies (Section 49.6.1).

49.5.4 Incidence of *Y. enterocolitica* in Foods

Pork. In contrast to the frequent occurrence of the bacterium in pigs and on freshly slaughtered carcasses, pathogenic *Y. enterocolitica* have only exceptionally been found from pork products at the retail sale stage, with the exception of fresh tongues.[61,63,177,180,217,243,262,268]

This phenomenon might be explained by the lack of proper selective methodology for the isolation of pathogenic strains; however, Wauters et al.[262] described a method that allowed *Y. enterocolitica* O:3 to be recovered from as many as 12 (24%) of 50 ground pork samples. Genetic probes can be used in DNA colony hybridization to demonstrate virulent *Y. enterocolitica* strains. The results of one such investigation indicate that traditional culture methods lead to underestimation of the presence of virulent *Y. enterocolitica* in pork products. A significantly higher detection rate (60%) was achieved when two isolation procedures[187,262] (Section 49.8.2) were combined with colony hybridization than when the isolation procedures were employed alone (18%).[180] In this study, counts of virulent yersiniae in pork sausage meat varied from 50 to 2,500 g^{-1}, and in pork cuts from 50 to 300 g^{-1}. A total of 150 samples of raw pork products from different slaughterhouses in Norway were analyzed by both a traditional culturing method[187] and a nested polymerase chain reaction (PCR) method.[130] *Y. enterocolitica* O:3 was isolated from two (1.3%) of the samples using the traditional method. The PCR results indicated the presence of pathogenic *Y. enterocolitica* in 39 (26%) of the samples.[116]

Ostroff et al.[192] showed in a case-control study that people with *Y. enterocolitica* infection reported having eaten significantly more pork or sausages than their matched controls. This might be explained by recontamination of sausages after pasteurization, bacterial multiplication during storage, and insufficient heat treatment in the kitchen.

Beef and Lamb. With a few exceptions,[45,265] cattle and sheep are generally not considered to be carriers of human pathogenic *Y. enterocolitica*. Nevertheless, the possibility exists of cross-contamination to beef or lamb from pig carcasses and pork in slaughterhouses, cutting plants, meat processing establishments, and butchers' shops. Beef is sometimes consumed after little or no heat treatment, and some concern has therefore been expressed about *Y. enterocolitica* contamination in beef. According to the case-control study of Ostroff et al.,[192] people with yersiniosis were more likely than controls to report a preference for eating meat prepared raw or rare.

In an extensive survey in Germany,[150] four strains of *Y. enterocolitica* and 6 of *Y. enterocolitica*-like bacteria were isolated from 37 samples of beef. Two of the beef isolates belonged to biovars that can cause typical human illness, but their virulence was not tested.[150] Environmental biovars of *Y. enterocolitica* were isolated from 15 of 61 samples of beef in Japan.[109] In the US, environmental biovars of *Y. enterocolitica* were recovered from 10 of 98 samples of vacuum-packaged beef and from 2 of 18 samples of vacuum-packaged lamb.[95] From a total of 100 samples of red meat, 50 each of beef and lamb from retail stores in Brisbane, Australia, only strains not harboring the virulence plasmid were obtained. Among the beef isolates, the strains belonged to *Y. enterocolitica* biovar 1A ($n = 21$), and *Y. frederiksenii* ($n = 4$), while the strains from lamb were categorized as *Y. enterocolitica* biovar 1A ($n = 12$), *Y. intermedia* ($n = 3$), and *Y. frederiksenii* ($n = 1$).[107] Ternström and Molin[243] found two nonvirulent *Y. enterocolitica* strains in 45 samples of beef.

Poultry. Stengel[228] isolated *Y. enterocolitica* serovars O:3 ($n = 3$), O:9 ($n = 3$), and nonvirulent *Y. enterocolitica* ($n = 13$) from 130 samples of poultry. This is probably the first time these virulent serovars have been isolated from poultry, and there was no obvious opportunity for cross-contamination from pork. Nevertheless, according to other investigations, poultry has not been proven to be a carrier of pathogenic *Y. enterocolitica*. Leistner et al.[150] isolated 35 strains of *Y. enterocolitica* and 56 related bacteria from 121 samples of chicken meat in Germany. Inoue and Nagao[110] recovered 16 strains of *Y. enterocolitica*-related bacteria from 40 samples of chicken in Japan. Nonvirulent *Y. enterocolitica* was also recovered from 3 of 75 turkey meat samples in the US[90] and from 2 poultry samples in Quebec, Canada.[49] Norberg[186] isolated 24 *Y. enterocolitica* strains from 82 samples of frozen chicken. The author regarded the isolates as environmental strains even though 1 of them agglutinated as serovar O:8. Unfortunately, no additional biotyping or virulence assay was done. Nesbakken et al.[181] failed to recover a single *Yersinia* isolate from a total of 360 poultry from eight flocks that were sampled by cloacal swabs in one poultry processing plant in Norway. In the US, 60 ready-to-cook broiler carcasses obtained from several local supermarkets were tested for the presence of *Yersinia enterocolitica*. None of the 16 *Y. enterocolitica* isolates was found to be presumptively virulent.[59]

Milk and Dairy Products. Worldwide studies indicate that *Y. enterocolitica* is fairly common in raw milk,[149] and several outbreaks of yersiniosis due to serovars O:3, O:6,30, O:8, O:10K, and O:13,18 have been associated with the consumption of milk or milk products.[12,30,52,88,170,239] *Y. enterocolitica* was isolated from ice cream[168] and pasteurized milk[214,274] as early as 1970.

Reported levels of raw milk contamination with *Y. enterocolitica* vary: Japan, 4%;[81] Denmark, 10%;[54] Australia, 16%;[107] Northern Ireland, 22%;[256] Morocco, 30%;[92] Italy, 37%;[72] Ireland, 39%;[208] and France, 81%.[254] Almost all reported isolates from raw milk samples have been categorized as nonvirulent environmental strains.

According to Greenwood et al.,[89] strains of *Yersinia* could be isolated from a sample of milk taken immediately after pasteurization but before bottling, even though the time/temperature conditions applied during pasteurization appeared to be adequate. The presence of *Y. enterocolitica* has been demonstrated also in pasteurized milk in other studies.[61,62,171,227] As *Y. enterocolitica* can grow in milk at refrigeration temperatures,[230] consumption of pasteurized milk contaminated with *Yersinia* constitutes a potential health risk. However, pasteurized milk, cheese made from pasteurized milk, and milk products such as ice cream prepared from pasteurized mixes should not pose a health problem unless recontaminated with *Y. enterocolitica*, because the pasteurization process usually is adequate to destroy *Y. enterocolitica*. In the study of Greenwood et al.,[89] it also proved that the bottles into which the pasteurized milk was filled were probably a source of contamination. None of the strains found were virulent.

DeBoer et al.[61] found 4 positive samples (4.5%) of 89 Brie and Camembert cheeses, and 1 positive sample (2.0%) of 50 blue veined cheeses. None of the isolated strains proved to be virulent. In another study,[92] 7 (7.4%) of 94 cheeses were contaminated with nonvirulent *Yersinia*, all the positive cheeses being made of raw milk.

In conclusion, it is almost solely in connection with outbreaks caused by contaminated pasteurized milk,[12,88,239] reconstituted powdered milk,[170] and contaminated chocolate milk[30] (Table 49–6) that one has been able to find the pathogenic strains. If not found in the product itself, epidemiological investigations have incriminated the product. In contrast, the screening of "normal" samples has most often only revealed nonvirulent strains. Nevertheless, the consumption of raw milk or dairy products made from raw milk may pose a potential public health problem.

Seafood. Some seafoods may be consumed raw, and thus the presence of virulent strains of *Y. enterocolitica* due to fecal contamination of water or contamination during processing could cause foodborne illness. The presence of environmental strains of *Y. enterocolitica* has been reported in fish,[11,61,124,204] mussels,[226] and oysters in Canada[247] and in the US.[149] *Y. enterocolitica*-like bacteria have been isolated from shrimp and crab from the Gulf of Mexico.[197]

Vegetables. Raw vegetables might be contaminated with feces from wild animals or from the use of animal or human wastes as fertilizer, and may constitute a health risk.[61] Contamination might occur also in a food processing plant when vegetables are washed and prepared, but it should be mentioned that vegetables are usually contaminated with large numbers of other bacteria and yeasts, and *Yersinia* is a poor competitor,[230] so extensive outgrowth of the organism is unlikely. However, a single outbreak of yersiniosis was caused by pickled vegetables in China.[15]

In France, *Y. enterocolitica* has been recovered from carrots, tomatoes, and green salads from hospital foods.[152] Some isolations have been made from vegetables in Czechoslovakia.[6] Thirty (46.1%) of 65 samples in a French study,[63] and 37 (43%) of 87 samples in one study from The Netherlands[61] were reported to be *Yersinia* positive. None of the isolated strains proved to be virulent.

49.6 EPIDEMIOLOGY

49.6.1 Infection with *Y. enterocolitica*

Sporadic Cases. *Y. enterocolitica* has been isolated from humans in many countries of the world, but it seems to be found most frequently in cooler climates (North America; the western coast of South America; Europe; northern, central, and eastern Asia; Australia; New Zealand; and South Africa).[8,122,166,267,268] The widespread nature of *Y. enterocolitica* has been well documented; by the mid 1970s, Mollaret and colleagues[166] had compiled reports of isolates from 35 countries on six continents. *Y. enterocolitica* infections are an important cause of gastroenteritis in the developed world, occurring particularly as sporadic cases in northern Europe[31,58] (Table 49–5), where a clustering of cases during autumn and winter has been reported.[267]

There are appreciable geographic differences in the distribution of the different phenotypes of *Y. enterocolitica* isolated from man (Section 49.2.2 and Table 49–4).[166] There is also a strong correlation between the serovars isolated from humans and pigs in the same geographical area.[22,68,196,219,258]

Serovar O:3 is widespread in Europe, Japan, Canada, Africa, and Latin America. Sometimes, but not always, phage typing makes it possible to distinguish between European, Canadian, and Japanese strains.[128,166] Serovar O:3 seems to be responsible for more than 90% of the cases in Denmark, Norway, Sweden, and New Zealand, and as many as 78.8% of the cases in Belgium in 1994 (Table 49–5). Serovar O:9/biovar 2 is the second most common in Europe, but its distribution is uneven; while it still accounts for a relatively high percentage of the strains isolated in France, Belgium, and the Netherlands, only a few strains have been isolated in Scandinavia.[267] However, recent data show that serovar O:9 is on the decrease in Belgium. In 1979–1981, this serovar was implicated in 23.3% of the cases, while in 1994 it was responsible for only 5.9% of the cases[162] (Table 49–5). A similar reduction has been seen also in France and The Netherlands [L. de Zutter, personal communication, 1996]. Until recently, the most frequently reported serovars in the US were O:8 followed by O:5,27.[29,166,190,269] In recent years, serovar O:3 has been on the increase in the US; O:3 now accounts for the majority of sporadic *Y. enterocolitica* isolates in California.[29] In 1989, the estimated cost of yersiniosis in the US was $138 million.[269]

The first Japanese case of *Y. enterocolitica* O:8 infection was linked to consumption of imported raw pork,[108] although O:8 infections from raw water have occurred also in Japan.[99]

The incidence of *Y. enterocolitica* infection in patients with acute endemic enterocolitis ranges from 0% to 4%, depending on the geographic location, study method, and population.[129] In Australia, Canada, Denmark, Germany, New Zealand, Norway, and Sweden (Table 49–5)[8,145,176,234,272] (Danish Zoonosis Centre, Copenhagen; National Institute of Public Health (Oslo), *Y. enterocolitica* has surpassed *Shigella*, and now rivals *Salmonella* and *Campylobacter* as a cause of acute bacterial gastroenteritis. Worldwide surveillance data show great changes over the last two decades. There appears to have been a real and generalized increase in incidence,[190,267,269] even though there is still much underreporting. Nevertheless, improvements in detection and reporting systems may have contributed a great deal to the increase in reported incidence.

Only a few epidemiological studies have been performed to investigate the sources of sporadic human infections. A 1985 study of *Y. enterocolitica* in Belgium identified consumption of raw pork as a risk factor for disease.[241] The following variables were found to be independently related to an increased risk of yersiniosis in a case-control study conducted in Norway: drinking untreated water, general preference for meat to be prepared raw or rare, and frequency of consumption of pork and sausages.[192] The infrequent occurrence of infections with *Y. enterocolitica* in some areas of the world may be due in part to avoidance of certain risk factors, such as lack of consumption of pork in Muslim countries.[212] Two seroepidemiological studies have indicated that occupational exposure to pigs may be a risk factor,[159,181] although in these two studies, confounders could not be excluded. Fecal-oral transmission from person to person may probably occur.[58]

Outbreaks. In the US, chocolate milk,[30] pasteurized milk,[239] soybean curd (tofu),[238] and bean sprouts[1]

Table 49–5 Incidence of Yersiniosis in Some Countries

Table 49–6 Outbreaks of Foodborne Disease Due to *Y. enterocolitica*

Outbreak		*Number of Persons*		*Mode of Transportation or Vehicle*	*Serovar*	*Reference*
Year	*Place*	*Ill*	*At Risk*			
1971	Karvina, Czechoslovakia (two nursery schools)	75	142	Unknown. Common food supplies to both nurseries		189
1972	Finland (hospital)	6	—	Nosocomial	0:9	246
1972	Japan (junior high school)	198	1,086	Unknown. Presumed common source	0:3, 0:5, 0:9	273
1972	Japan (community outbreak)	189	441	Unknown	0:3	16
1972	Japan (community outbreak)	544	1,042	Unknown	0:3	16
1972	North Carolina (intrafamilial)	16	21	Sick puppies	0:8	91
1974	Japan (school)	296	814	Unknown	0:3	155
1975	Japan (school)	145	486	Unknown	0:3	155
1976	New York	222	2,193	Contaminated chocolate milk	0:8	30
1979	Japan (school)	184	954	Unknown	0:3	155
1979	Japan (institution)	6	92	Unknown	0:3	155
1980	Japan (school)	1,051	8,835	Unknown	0:3	155
1980	Newfoundland, Canada (hospital)	9	—	Nosocomial	0:5	207
1981	Canada (family outbreak)	3	4	Unknown. River water?	0:21	154
1981	Japan (school)	641	1,812	Unknown	0:3	155
1981	New York State (summer diet camp)	239	455	Reconstituted powdered milk dispenser or chow mein	0:8	170
1981–1982	Washington	44		Tofu-plant. Spring water source contaminated	0:8	238
1982	Tennessee, Arkansas, Mississippi	>172	—	Pasteurized milk	0:13,18	239
1982	Pennsylvania (Brownie troop)	16	33	Bean sprouts grown in water from contaminated well	—	1
1984	Canada	3	4	Well water	0:3	245
1984	Japan (school)	102	902	Unknown	0:3	155
1984–1985	UK (pediatric wards of hospital)	36	—	Pasteurized milk	0:10K 0:6,30	88
1985	New York (four-infant cluster)	4	4	Unknown. No obvious common exposure	0:3	137
1987	Shengyang, China (school)	351	—	Pickled vegetables	0:3	15
1988	Kristianstad, Sweden	75	—	Pasteurized milk	0:3	12
1988	Georgia (infants and children)	15	—	Household preparation of chitterlings	0:3	146
1994	Västernorrland, Sweden	13	—	Unknown, pork?*	0:3	234
1994–1995	Buffalo, New York	12	—	Pork chitterlings	0:3	136
1995	Upper Valley of Vermont, New Hampshire	10	—	Pasteurized milk	0:8	52
1995–1996	Buffalo, New York	17	—	Pork chitterlings	0:3	136

* pork is probably the vehicle (B. de Jong, personal communication, 1996)

have been implicated as sources in outbreaks of *Y. enterocolitica* infection (Table 49–6). These three outbreaks, all of which occurred before 1983, were caused by *Y. enterocolitica* serovars that have been infrequently associated with human disease (serovars O:13, O:18) or that no longer predominate in the US (serovar O:8). More recently, the preparation of raw pork intestines (chitterlings) was associated with outbreaks of *Y. enterocolitica* O:3 infections among black US infants;[136,146] the organism was isolated from samples of the pork intestines.

The milkborne outbreak in Sweden in 1988[12] was caused probably by recontamination of pasteurized milk because of lack of chlorination of the water supply. In the multistate outbreak in 1982,[239] milk cartons were contaminated with mud from a pig farm.[18] In the case of the outbreak described by Greenwood and Hooper,[88] postpasteurization contamination may have occurred from bottles. Previous studies have shown that milk-associated *Y. enterocolitica* outbreaks have been linked to the addition of ingredients after pasteurization.[30,170]

In 1981, an outbreak of infection due to *Y. enterocolitica* O:8 in Washington State occurred in association with the consumption of tofu packed in untreated spring water.[238] The outbreak serovar was isolated from the spring water samples. Another outbreak caused by serovar O:8 was traced to ingestion of contaminated water used in manufacturing or preparation of food.[217] Two other *Yersinia* outbreaks have been associated with well water. One occurred among members of a Pennsylvania girl scout troop after they ate bean sprouts grown in contaminated well water;[1] the other was a familial outbreak of yersiniosis in Canada.[245]

The epidemiology of yersiniosis in the US seems to have evolved into a pattern similar to the picture in Europe,[29,36,190] where foodborne *Yersinia* outbreaks are rare and where serovar O:3 predominates.[166,201,253] Although yersiniosis appears to be more common in Europe than in the US, only five foodborne outbreaks have been reported in Europe.[12,88,189,234,246]

49.6.2 Epidemiological Tools

Methods that have been used to differentiate pathogenic isolates of *Y. enterocolitica* include biotyping,[264] serotyping,[7,259] antibiogram typing,[20,56] phage typing,[20,167,183] and multilocus enzyme electrophoresis.[51] Methods based on the characterization of the genotype include plasmid profile analysis, restriction enzyme analysis of plasmid and chromosomal DNA (DNA fingerprinting), pulsed-field gel electrophoresis (PFGE),[44,172,211] and the use of DNA or RNA probes.[14,156,242,255]

In a comparison of six methods for typing *Y. enterocolitica*,[128] antimicrobial susceptibility had the greatest overall discriminatory power, followed by restriction enzyme analysis of chromosomal DNA (REAC), H-antigen typing, restriction enzyme analysis of plasmid DNA (REAP), phage typing, and biotyping (in decreasing order of discrimination) (Table 49–7). Antimicrobial susceptibility testing is a highly standardized method employed in a large number of laboratories; however, susceptibility patterns may be influenced by local antibiotic usage, which may make differentiation of outbreak strains from epidemiologically unrelated strains difficult. On the basis of the investigation of strains from three outbreaks, Baker and Farmer[20] concluded that even though antimicrobial susceptibility testing contributed to the differentiation of the isolates, results were less reliable than those obtained by serotyping and phage typing. Using multilocus enzyme electrophoresis to investigate allelic variations in the chromosomal genomes of the same strains would have given an overall discrimination index of 0.752, indicating the method to be less suitable than antimicrobial susceptibility for tracing epidemiologically related *Y. enterocolitica* strains.[51] The discriminatory power of the genotypic methods was greatest within serovar O:8 (Table 49–7). Because this serovar is homogeneous with regard to biovar and phagevar, there has long been a need for methods that permit a finer degree of differentiation in epidemiological investigations.[20] A bacteriophage typing system that allows greater differentiation of O:8 strains has been described.[20] The results also show that restriction enzyme analysis is an effective method for the analysis of serovar O:8. Some studies demonstrate clearly the high discriminative power of PFGE toward the differentiation of highly related *Y. enterocolitica* strains that belong to the same biovar/serovar.[70,74,97] But a comparison between PFGE and the methods used in Table 49–7 is still missing.

49.6.3 Infection with *Y. pseudotuberculosis*

Like *Y. enterocolitica*, *Y. pseudotuberculosis* is also isolated most frequently in cooler climates.[8] In the developed part of the world, *Y. pseudotuberculosis* infections do not play any significant role; however, the bacterium is found in wild animals as well as in pets.[8,9] The serovars isolated from animals are identical with those detected in humans, suggesting that the source of human *Y. pseudo-*

tuberculosis infections can be found in domestic and wild animals and birds.[8]

Because *Y. pseudotuberculosis* is so common in animals, their feces are quite likely to contaminate soil, water, and vegetables and thus contribute to transmission to man.[8,9] The view that *Y. pseudotuberculosis* may be a cause of foodborne diseases probably has been encouraged by reports of its survival on and isolation from vegetables[5] as well as the occurrence of family outbreaks.[205]

Water and soil in Japan and the far eastern regions of Russia are contaminated with *Y. pseudotuberculosis*.[78] Unchlorinated drinking water from wells, springs, and streams in mountainous areas was considered to have caused an epidemic outbreak and sporadic infections with *Y. pseudotuberculosis* in Japan.[78,79,111] Transmission of *Y. pseudotuberculosis* to humans through water contaminated by feces from wildlife and domestic animals has been reported.[76,77]

49.7 FACTORS AFFECTING SURVIVAL AND GROWTH OF *Y. ENTEROCOLITICA*, PARTICULARLY IN FOODS

Y. enterocolitica is a facultative organism able to multiply in both aerobic and anaerobic conditions.

49.7.1 Temperature

The ability of *Y. enterocolitica* to multiply at low temperatures is of considerable concern to food producers (Figure 49–1). The reported growth range is –2° C to 42° C.[23,84] Optimum temperature is 28° C to 29° C.[23] *Y. enterocolitica* can multiply in foods such as meat and milk at temperatures approaching and even below 0° C.[93,149,229,230] It is important to recognize the rate at which *Y. enterocolitica* can multiply, which is considerably greater than that for *L. monocytogenes*[27] (Table 49–8). Results show that, in a food with a neutral pH stored at 5° C, *Y. enterocolitica* counts may increase from $10\ \text{ml}^{-1}$ to $2.8 \times 10^{7}\ \text{ml}^{-1}$ in 5 days.

49.7.2 pH

The minimum pH for growth has been reported as being between 4.2 and 4.4,[132] while in a medium in which the pH had been adjusted with HCl, growth occurred at pH 4.18 and 22° C.[42] The results in Table 49–9 show the ability of *Y. enterocolitica* to multiply at pH 4.6 and give an indication of the extent to which growth occurs in 6.5% NaCl.[232]

The presence of organic acids will reduce the ability of *Y. enterocolitica* to multiply at low pH, acetic acid being more inhibitory per gram mol at a given pH than lactic and citric acids.[42]

49.7.3 Other Factors Singly and in Combination

The effect of lactic acid (concentration range of 0.1 to 1.1% v/v within a pH range of 3.9 to 5.8 at 4° C) on *Y. enterocolitica* O:9 is greater under anaerobic than aerobic conditions, although the bacterium has proved to be more tolerant of low pH conditions under anaerobic atmosphere than under an aerobic atmosphere in the absence of lactic acid.[67] *Y. enterocolitica* is not able to grow at pH <4.2 or

>9.0[132,229] or at salt concentrations greater than 7% (a_w <0.945).[229]

49.7.4 Growth and Survival in Foods

The ability to propagate at refrigeration temperature in vacuum-packed foods with a prolonged shelf-life[94,95] is of considerable significance in food hygiene. *Y. enterocolitica* may survive in frozen foods for long periods.[217]

The organism does not survive pasteurization or normal cooking (ie, boiling, baking, frying) temperatures. Heat-treatment of milk and meat products at 60° C for 1 to 3 min effectively inactivates *Y. enterocolitica.*[149] *D*-values determined in scalding water were 96, 27, and 11 seconds at 58° C, 60° C, and 62° C, respectively.[237]

The literature is contradictory regarding the multiplication of *Y. enterocolitica* in meat during conventional cold storage.[33,75,93,133,149,217,229,230] A comparison of published[96] and predicted generation times (GT)[232] for *Y. enterocolitica* in raw pork at 7° C, 0.5% (w/v) NaCl, and pH 5.5–6.5 shows GTs of 8.4 to 12.4 hours (published) and 8.15 to 5.05 hours (predicted). However, according to many reports, the ability of *Y. enterocolitica* to compete with other psychrotrophic organisms normally present in food may be poor.[75,133,217,230] In contrast, a number of studies have shown that *Y. enterocolitica* is able to multiply in foods kept under chill storage and might even compete successfully.[33,84,87,93,149,151,229] Pig carcasses are often held in chilling rooms for 3 to 4 days after slaughter prior to cutting. Prepackaged raw meat products may remain in retail chill cabinets for more than a week, depending on the product, packaging, package atmosphere, and rate of turnover. Pathogenic variants of *Y. enterocolitica* might multiply considerably during the course of this relatively long storage period.

As a facultative organism, the growth of *Y. enterocolitica* is drastically affected by a gaseous atmosphere. Under anaerobic conditions, *Y. enterocolitica* is unable to grow in beef at pH 5.4 to 5.8, whereas growth occurs at pH 6.0.[87] 100% CO_2 is reported to inhibit the growth of *Y. enterocolitica.*[84,164] In the study of Gill and Reichel,[84] *Y. enterocolitica* was inoculated into high pH (>6.0)

Table 49–9 Experimentally Determined Generation Times (GT) for *Y. enterocolitica*

Temperature (° C)	*pH*	*NaCl*	*NO_2*	*GT (h)*
5	5.5	2.5	0	14.76
10	6.0	6.5	0	21.18
15	7.0	0.5	0	1.67
25	4.6	0.5	0	2.15

Three strains were used, one serovar O:3 and two serovar O:5,27.

beef DFD (dark firm dry)-meat. Samples were packaged under vacuum or in an oxygen-free CO_2 atmosphere maintained at atmospheric pressure after the meat had been saturated with the gas and stored at -2° C, 0° C, 2° C, 5° C, or 10° C. In vacuum packs, *Y. enterocolitica* grew at all storage temperatures at rates similar to or faster than those of the spoilage flora. In CO_2 packs, the bacterium grew at both 5° C and 10° C, but not at lower temperatures.

Mohammad and Draughon[163] investigated the growth characteristics of *Y. enterocolitica* strains in pasteurized milk at 4° C. Pasteurized milk was inoculated with 10 or 1,000 cells ml^{-1} of *Y. enterocolitica*. *Y. enterocolitica* competed well with the background microflora and reached log numbers of 5.0 to 7.0 ml^{-1} after 7 days; however, a study of Stern et al.[230] indicated that while *Y. enterocolitica* has the capacity for growth in milk at refrigeration temperatures, it is a poor competitor with common spoilage organisms.

49.7.5 Survival and Inactivation in Water

Survival in Untreated Water. The 3-log reduction (99.9% inactivation) time for *Y. enterocolitica* in lake water has been reported to be 17 to 18 days at 4° C and 14 to 15 days at 10° C; the bacterium possibly surviving for a longer time in cold, clean surface waters than *E. coli*.[153] A Polish study described an inactivation time (T_{100}) of 38 days at spring temperatures and 7 days under summer conditions in unfiltered water, in contrast to 197 and 184 days, respectively, in filtered water.[65] Some strains of *Y. enterocolitica* are even able to grow in water at low temperatures (4° C).[102]

Inactivation in Chlorinated Water. In the study of Lund,[153] autoclaved tap water (pH 6.5) was chlorinated according to conventional water-treatment practices, resulting in a free residual level of approximately 0.05 mg l^{-1} after a contact time of 30 minutes. A 3-log reduction for *Y. enterocolitica* and *E. coli* exposed to 0.2 mg l^{-1} Cl_2 was obtained in 20 to 180 and 20 to 25 seconds, respectively, depending on bacterial strain, plasmid content (*Y. enterocolitica* O:3 harboring a 40 to 50 Mdal virulence plasmid exhibits enhanced resistance to chlorine), and temperature.[153]

Inactivation by Ultraviolet (UV) Radiation. The UV radiation dose at 254 nm required for a 3-log reduction (99.9% inactivation) of *Y. enterocolitica* O:3 and *E. coli* is 2.7 and 5.0 mWs cm^{-2}, respectively. Using *E. coli* as the basis for comparison, it appears that *Y. enterocolitica* O:3 is more sensitive to UV than many of the pathogens associated with waterborne disease outbreaks and can be inactivated readily in most commercially available UV reactors.[46] In contrast, Carlson et al.[50] demonstrated that avirulent strains were more sensitive to UV radiation (3-log dose of 7 to 10 mWs cm^{-2}) than a virulent *Y. enterocolitica* O:8 strain, which contained plasmids of 41 and 73 Mdal (3-log dose of 22 mWs cm^{-2}).

49.8 PRINCIPLES OF DETECTION AND ISOLATION

49.8.1 General Principles

To isolate *Y. enterocolitica* from foodstuffs, methods other than those used for isolation from patients with acute intestinal infection are in part required.[120,158,215,217] This is mainly due to four factors:

1. The background flora in foodstuffs varies considerably, both with regard to number and species distribution.
2. The *Yersinia* count in foods usually is far less than in clinical samples. The inclusion of an enrichment step in the isolation procedure is therefore required.
3. The bacteria may be sublethally damaged after exposure to cold, heat, or chemicals. This may necessitate a resuscitation step.
4. A broad range of different *Yersinia* is usually found in foods, and most of these strains are of no particular clinical significance.[120,149] An isolation method that as far as possible specifically selects pathogenic variants is desirable therefore.

The individual biovars and serovars of *Y. enterocolitica* differ in their tolerance to selective agents and to the conditions encountered during the isolation process. The choice of procedure will thus have a considerable influence on the range of bacteria isolated. Differences in tolerance occur between the different pathogenic serovars (O:3, O:8, and O:9).[217] A method for the isolation of pathogenic *Y. enterocolitica* strains that works well for one serovar may not necessarily be effective for another.

49.8.2 Specific Procedures for the Detection and Isolation of *Y. enterocolitica*

A three-step method based on a combination of cold enrichment in a medium with low selectivity and subsequent inoculation into a highly selective medium has been developed for the Nordic Committee on Food Analysis.[187] The method, a reference method that can be employed for the qualitative demonstration of Y. *enterocolitica* in all types of foods, comprises three steps:

1. Three hours resuscitation at 20° C to 25° C in phosphate buffered saline (pH 7.6) with 2% sorbitol and 0.15% bile salts (PSB)
2. 8 days pre-enrichment in PSB at 4° C followed by selective enrichment in a modified Rappaport broth (MRB) (4 days at 20° C to 25° C)
3. 3 weeks' cold enrichment at 4° C in PSB.

After each step, culture is carried out on cefsulodin-irgasan-novobiocin (CIN) agar, a highly selective and differential medium that is more effective than conventional enteric media for the recovery of Y. *enterocolitica*.[100] After incubation at 28° C for 18 to 20 hours, Y. *enterocolitica* appears as 0.5- to 1.0-mm-diameter colonies with a dark red "bull's eye" and transparent border. CIN agar permits the growth of all pathogenic serovars.

Wauters et al.[262] developed a method for isolation of serovars O:3 and O:9 from meat and meat products. The procedure is based on a 2- to 3-day selective enrichment period in irgasan-ticarcillin-potassium chlorate (ITC) enrichment broth at room temperature, and is therefore very time-saving compared with the method described above. Culture is carried out on modified Salmonella-Shigella agar with 1% sodium deoxycholate and 0.1% $CaCl_2$ (SSDC). Under practical conditions, the method has proved effective for the detection of serovars O:3 and O:9, but not particularly satisfactory with regard to Y. *enterocolitica* serovar O:8 and environmental strains.[262]

Both Y. *enterocolitica* and Y. *pseudotuberculosis* seem to be more tolerant of alkaline conditions than most other *Enterobacteriaceae*, and treatment of food enrichments with potassium hydroxide (KOH) may be used to selectively reduce the level of background flora.[19] Tolerance of high pH is influenced by the suspending medium, temperature, and phase of growth;[216] however, despite some improvements in the conditions provided during exposure to high pH, a method based on treatment with KOH proved inferior to selective enrichment in bile-oxalate-sorbose broth for recovering pathogenic strains of Y. *enterocolitica* from inoculated foods.[216] Elements of the methods from the Nordic Committee on Food Analysis,[187] Schiemann,[215] Wauters,[262] and KOH treatment[216] are incorporated into the International Organization for Standardization (ISO) method (ISO 10273) (Figure 49–2).[113]

Genetic probes can be used in DNA colony hybridization to demonstrate virulent Y. *enterocolitica* strains.[123,242,255] Probes based on cloned fragments that encode for virulence factors, and synthetic oligonucleotide probes based on sequence analysis of the cloned fragments, are available.[86,103,114,123,180] A study[180] in which gene probes and colony hybridization were used following isolation either by the method of Wauters et al.[262] or the Nordic Committee on Food Analysis method[187] showed that a substantial increase in the rate of detection of pathogenic Y. *enterocolitica* could be achieved. Isolation plus hybridization increased the detection rate from 16% to 38% for the method according to Wauters et al., and from 10% to 48% for the Nordic method. The results of this investigation[180] support the supposition that conventional culture methods lead to underestimation of virulent Y. *enterocolitica* in pork products.

Wren and Tabaqchali[271] developed a simple PCR assay using oligonucleotide primers based on nucleotide sequences from two independent virulence genes that readily distinguish between virulent and nonvirulent Y. *enterocolitica*. A double PCR procedure has also been developed based on a single virulence gene on the virulence plasmid.[130]

Rasmussen et al.[206] detected Y. *enterocolitica* O:3 in fecal samples and tonsil swabs from pigs using immunomagnetic separation and PCR. O:3 cells were detected after pre-enrichment, but direct detection needed further optimization of the sample preparation procedures.

Methods for the isolation of Y. *enterocolitica* from water usually involve concentration by filtration followed by procedures similar to those used for isolation from food.[113,187,215,262]

49.8.3 Specific Comments on Procedures for the Detection and Isolation of Y. *pseudotuberculosis*

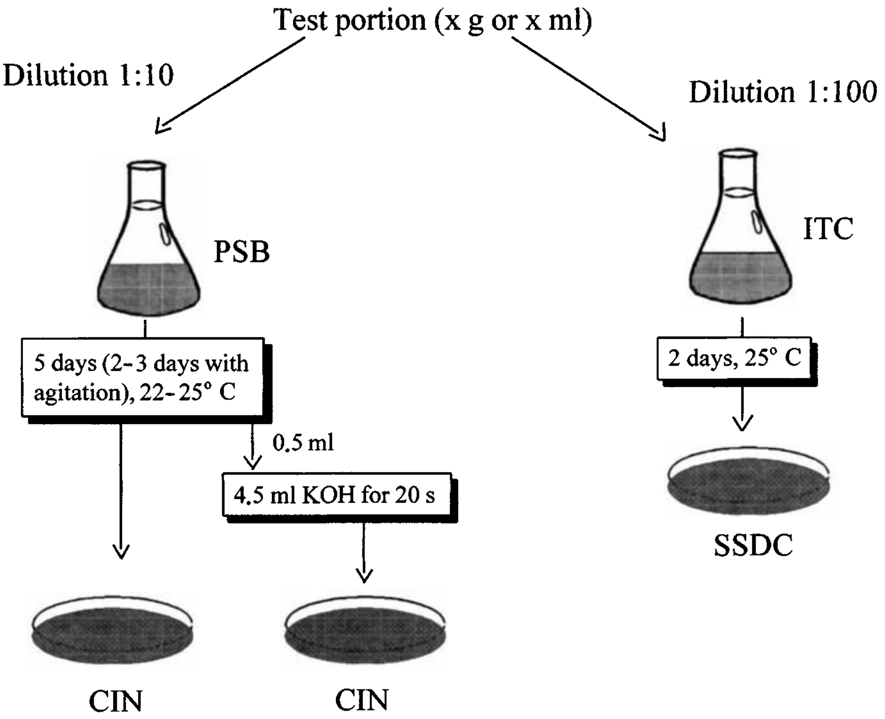
The same enrichment procedures as for Y. *enterocolitica* have proved suitable for Y. *pseudotuberculosis*,[8] and treatment of food enrichments with KOH may also be used to selectively reduce the level of background flora.[19,79]

Culture should be carried out on MacConkey agar or CIN agar. According to H. Fukushima [personal communication, 1990], cefsulodin inhibits the growth of Y. *pseudotuberculosis* at the concentrations used in CIN agar, and consequently, cefsulodin should be omitted from the medium in this case. SSDC agar is not suitable as a culture medium for Y. *pseudotuberculosis*.[8]

49.9 CONTROL

49.9.1 At the Farm Level

Newborn piglets are colonized easily and become long-term healthy carriers of Y. *enterocolitica* in the



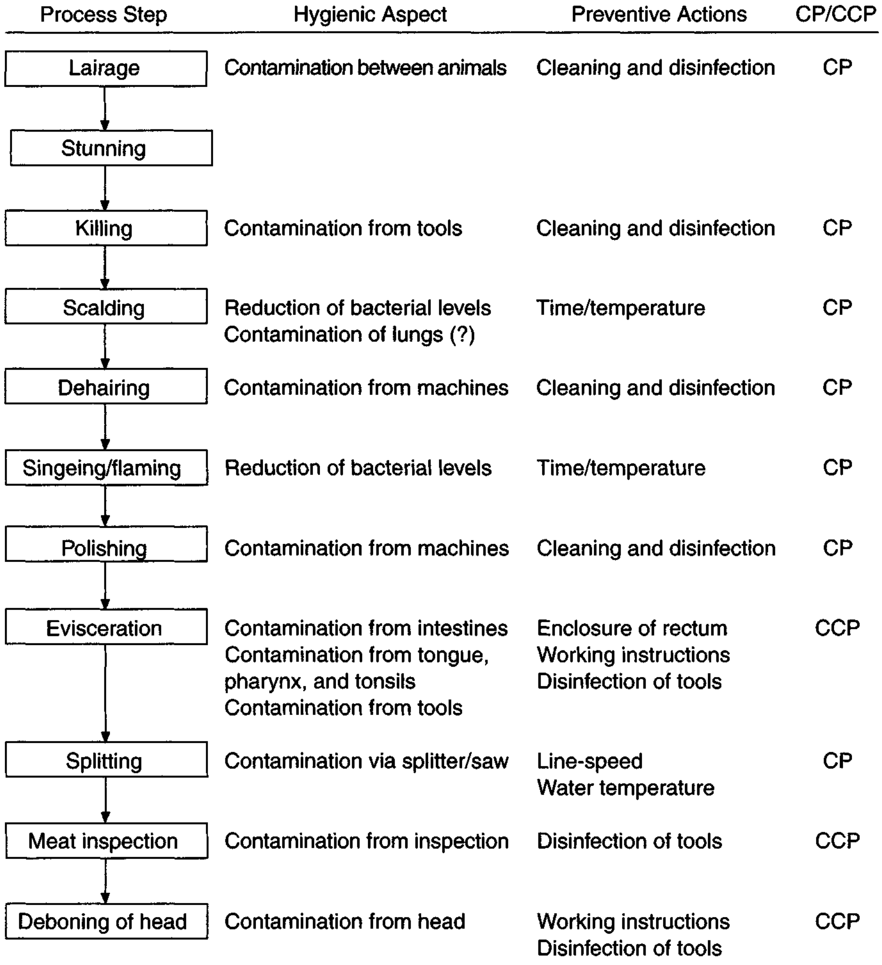
PSB = phosphate-buffered saline and sorbitol, 2%; bile salts, 0.15%. ITC = irgasan-ticarcillin-potassium chlorate enrichment broth. KOH = KOH, 0.25% (w/v); NaCl, 0.85% (w/v) in water. CIN = cefsulodin-irgasan-novobiocin agar. SSDC = Salmonella-Shigella + sodium deoxycholate, 1%; $CaCl_2$, 0.1%.

Figure 49–2 Method for Qualitative Recovery of *Y. enterocolitica* from Foods Recommended by the International Organization for Standardization (ISO)(ISO 10273).[113] The method comprises elements of the methods from the Nordic Committee on Food Analysis,[187] Schiemann,[215] Wauters,[262] and the treatment with KOH.[216]

oral cavity and intestines.[217] In a recent study,[222] an ELISA[184] was used to detect IgG antibodies against *Y. enterocolitica* O:3 in sera from 1,605 slaughter pigs from 321 different herds. Positive titers were found in 869 (54.1%) of the samples. Of the 287 herds in the final epidemiological study, 182 (63.4%) of the herds were defined as positive herds. Among the positive herds, there were significantly fewer combined herds of piglets and fatteners (53.1%) than fattening herds (88.1%). Multiple logistic regression detected several factors related to management and hygiene influencing the risk for antibody detection of *Y. enterocolitica* O:3.[222] The farm vehicles used for transport of slaughter pigs to abattoirs, daily observation of cats with kittens at the farm, and using straw for slaughter pigs increased the risk. The overall results indicate that the infection follows the live pig, and the study indicates that it is possible to establish *Y. enterocolitica* O:3 free segments of the population. Most important is to limit the contact between infected and noninfected herds by avoiding the transfer of animals from the infected to noninfected populations. Pig production is a typical pyramid structure, where a small number of herds supply the next production strata. If a successful reduction could be accomplished on the top levels of the pyramid, the results from this study suggest that a marked lowering of prevalence might be obtained in the general pig population.

49.9.2 During Slaughter

It is not possible to sort out pigs contaminated with *Y. enterocolitica* at postmortem meat inspection. Pig slaughter is an open process with many opportunities for the contamination of the pig carcass with *Y. enterocolitica*, and it does not contain any point where hazards are completely eliminated (Figure 49–3).[34] Contamination of the carcass with *Y. enterocolitica* during pig slaughter is most likely to arise from fecal and pharyngeal sources.[13,175] HACCP (Hazard Analysis Critical Control Point) and GMP (Good Manufacturing Practice) in pig slaughter must be focused on limiting this spread. As a guide, attention should be given to the possible establishment of critical points or critical control points at the following specific steps during slaughter and dressing (Figure 49–3):



Process Step	Hygienic Aspect	Preventive Actions	CP/CCP
Lairage	Contamination between animals	Cleaning and disinfection	CP
Stunning			
Killing	Contamination from tools	Cleaning and disinfection	CP
Scalding	Reduction of bacterial levels Contamination of lungs (?)	Time/temperature	CP
Dehairing	Contamination from machines	Cleaning and disinfection	CP
Singeing/flaming	Reduction of bacterial levels	Time/temperature	CP
Polishing	Contamination from machines	Cleaning and disinfection	CP
Evisceration	Contamination from intestines Contamination from tongue, pharynx, and tonsils Contamination from tools	Enclosure of rectum Working instructions Disinfection of tools	CCP
Splitting	Contamination via splitter/saw	Line-speed Water temperature	CP
Meat inspection	Contamination from inspection	Disinfection of tools	CCP
Deboning of head	Contamination from head	Working instructions Disinfection of tools	CCP

Figure 49–3 Hygienic Aspects and Preventive Actions with Respect to *Yersinia enterocolitica* during Pig Slaughter. CP, critical point; CCP, critical control point. *Source:* Adapted with permission from E. Borch, T. Nesbakken, and H. Christensen, Hazard Identification in Swine Slaughter with Respect to Foodborne Bacteria, *International Journal of Food Microbiology,* Vol. 30, pp. 9–25, 1996, © Elsevier Applied Science.

1. lairage
2. killing
3. scalding
4. dehairing
5. singeing/flaming
6. scraping/polishing
7. circumanal incision and removal of the intestines
8. excision of the tongue, pharynx, and in particular the tonsils
9. splitting
10. postmortem meat inspection procedures
11. deboning of the head.

Some of the above-mentioned critical control points will be discussed in more detail below.

During lairage, pathogenic *Y. enterocolitica* may spread from infected to noninfected pigs.[80] If possible, herds should be handled separately, and cleaning and disinfection of the lairage facilities should be performed between herds because some herds are free from this pathogen.[222]

A working procedure that is employed in many slaughterhouses, and that can be introduced immediately in all slaughterhouses, is the two-knife method. This can be used to interrupt the path of infection from oral cavity and intestine to other parts of the carcass. The two-knife method involves the installation in the slaughter hall of knife decontaminators, with running water held at a temperature of approximately 82° C. When an unclean working operation has been performed, for example, in the region around the rectum or oral cavity, the knife is rinsed before being placed in the decontaminator. The operator should then wash his or her hands before the other knife is used for clean working operations. The two-knife method should be used both by slaughtermen and meat inspection personnel.

Meat inspection procedures concerning the head also seem to represent a cross-contamination risk. Incision of the submaxillary lymph nodes is a compulsory procedure according to the regulations of the European Union (EU).[69] This may, however, result in the bacterium being transported from the tonsillar region to other parts of the carcass by the knives and hands of the meat inspection personnel.[175] In view of the fact that the incidence of tuberculosis in pigs and humans has been reduced to a very low level in many parts of the world, it may be possible to reconsider regulations that require incision of the submaxillary lymph nodes by meat inspectors.

Cutting and removal of head-meat in pigs should be carried out on a separate work table, preferably in a separate room.[69] This room should be considered to be an unclean area. Knives and equipment must not be used for cutting and deboning other parts of the carcass without prior cleaning and disinfection. Current EU regulations that require removal of pig head-meat to be carried out in a separate department are unfortunately not complied with in all abattoirs.

The possibility of decapitation early on in the carcass dressing procedure has been considered, with the head, including tongue and tonsils, then being removed on a separate line for heat treatment and cutting.[55] The results presented by Andersen[13] indicate, however, that it is even more important to modify procedures for removal of the guts to avoid contamination of the carcass from the rectum. Technological solutions have been found that allow removal of the rectum without soiling of the carcass. This can be done by insertion of a prefrozen plug into the anus prior to rectum-loosening and gut removal.[60] The sealing off of the rectum with a plastic bag immediately after it has been freed can significantly reduce the spread of *Y. enterocolitica* to pig carcasses[13,182] (Figure 49–4). According to data from the Norwegian National Institute of Public Health, the occurrence of human yersiniosis has dropped after the introduction of the plastic bag technique in about 90% of the pig slaughterhouses in Norway (Figure 49–5). In 1997, the number of reported cases in Norway was 108, corresponding to a decline of more than 40% since 1994. A similar drop in yersiniosis (about 30%) has been seen in Sweden after the introduction in this technique.[234]

49.9.3 During the Processing of Meat Products

In addition to the slaughter hall and the cutting and deboning departments, the sausage-making department must also be considered to be a contaminated area. It must be assumed that raw materials such as pig head-meat and pork cuts, and consequently also sausage meat, are likely to be contaminated with pathogenic *Y. enterocolitica*. Strict cleaning and disinfecting requirements must therefore also apply here. It is important to maintain an effective separation between sausage preparation and packing to avoid recontamination after heat treatment.

49.9.4 During Sale and Catering

Refrigeration. *Y. enterocolitica* is able to multiply at temperatures approaching 0° C. Although refrigeration of food does not prevent the multiplication of *Y. enterocolitica*, the rate at which this takes place will be reduced.

Separation of Raw Meats from Other Foods. Raw meats (in particular pork) should be separated from other foods. Cross-contamination from raw meat to heat-treated end products must be avoided in meat-processing establishments, butchers' shops, meat departments in retail food stores, and in kitchens in institutions, restaurants, and homes.

Cleaning and Disinfection. Knives, equipment, and machines used to cut or process raw meat products must be cleaned and disinfected before being used for handling other foods. All surfaces that have been in contact with raw meat must be cleaned and disinfected with appropriate and effective agents.

Adequate Cooking of Meat. A case-control study carried out in Norway revealed that inadequate heat treatment of meat is a risk factor for human yersiniosis.[192] Consumption of undercooked pork should be discouraged.

Pasteurization of Milk. Well-controlled pasteurization of milk is necessary to safeguard against *Y. enterocolitica* as well as many other pathogens.

Kitchen Hygiene. Information to the public on the consequences of eating raw and lightly cooked foods, and of the need for proper kitchen hygiene, will thus be a most important prophylactic measure. Good hygiene is particularly necessary because *Y. enterocolitica* is able to multiply at refrigeration temperature.

Personal Hygiene. Precautions aimed at preventing fecal-oral spread of the pathogens should be taken. Hand-washing and proper stool disposal must be employed in household, day-care, and hospital settings.

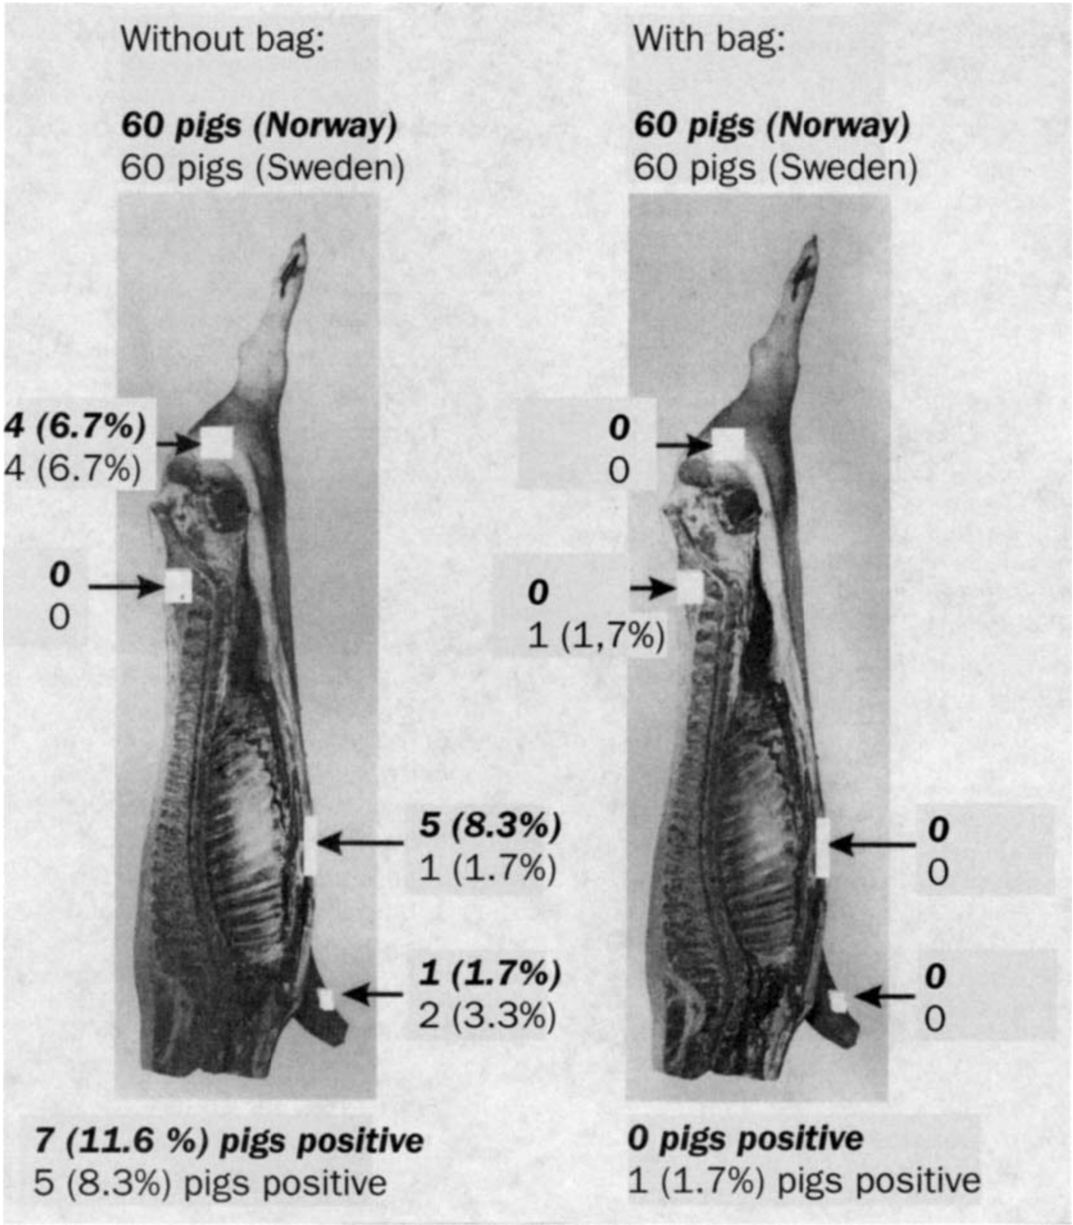


Figure 49–4 Occurrence of *Y. enterocolitica* O:3 on Pig Carcasses Eviscerated with and without a Plastic Bag To Seal Off the Rectum in one Norwegian and one Swedish Slaughterhouse. *Source:* Reprinted with permission from T. Nesbakken et al., Reduction of *Yersinia Enterocolitica* and *Listeria* spp. on Pig Carcasses by Enclosure of the Rectum during Slaughter, *International Journal of Food Microbiology,* Vol. 23, pp. 197–208. © 1994, Elsevier Applied Science.

Animal Contact. Avoidance of contact with excreta from pigs or domestic pets may reduce transmission. Domestic animals should be kept away from food preparation areas.

49.9.5 Water Supplies

Evidence discussed earlier indicates that wild and domestic animals might carry strains of *Y. enterocolitica* that are pathogenic to humans. It is therefore important not to drink from raw water supplies that are liable to contamination by animals, leakage from septic tanks, or open latrines, not to allow such water supplies to be used in food production, and to ensure that drinking water supplies are treated effectively so that *Y. enterocolitica*, and the multitude of other pathogens, are inactivated or eliminated.

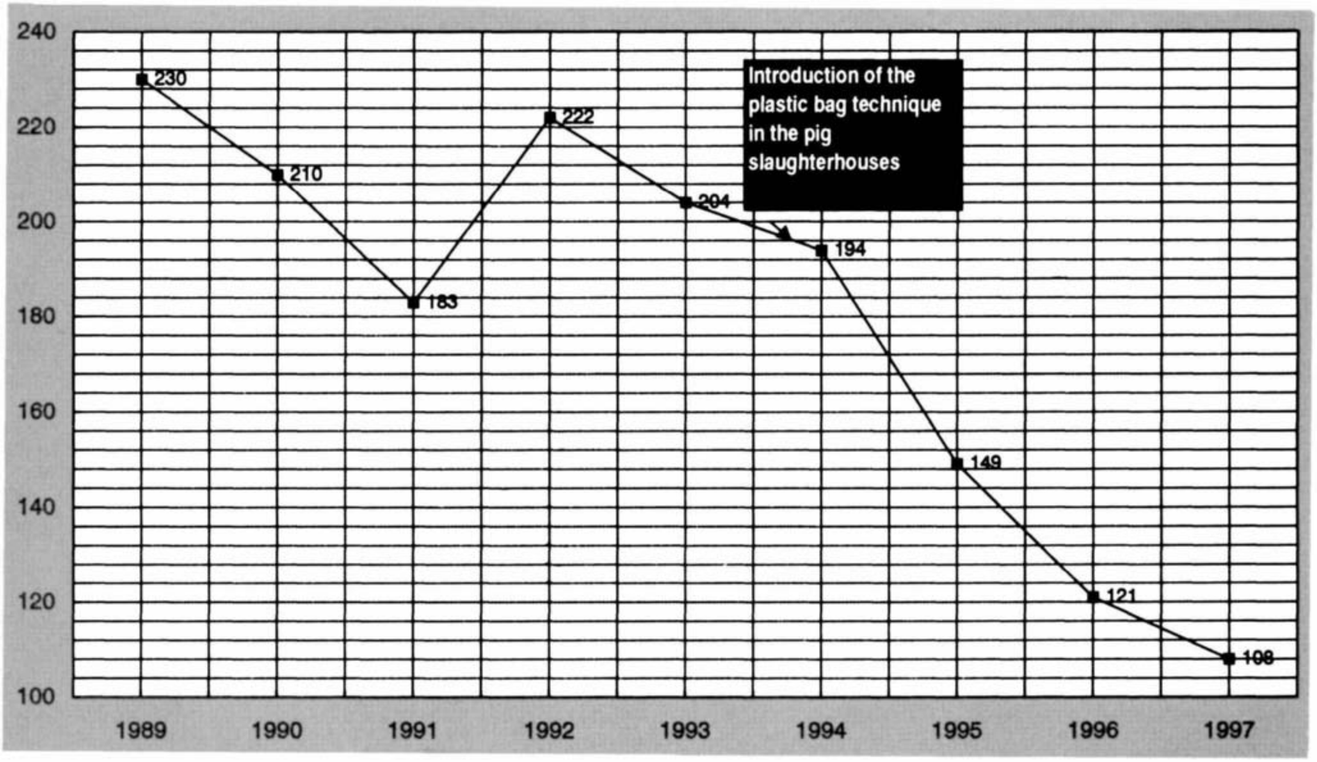

Figure 49–5. Number of Reported Cases of *Yersiniosis* in Norway. In 1994, the pig slaughterhouses in Norway started sealing off the rectum with a plastic bag. *Source:* Reprinted from National Institute for Public Health, Oslo.

49.10 CONCLUDING REMARKS

The consequences of yersiniosis are severe and include prolonged acute infections, pseudoappendicitis, and long-term sequelae such as reactive arthritis and erythema nodosum, particularly in northern Europe where the prevalence of the HLA-B27 histocompatibility type is high.[4,58,129,236,266] These consequences make *Y. enterocolitica* infection a public health and economic problem of greater magnitude than the actual number of recorded cases would suggest.[191]

The emergence of yersiniosis is related to changes that have occurred in livestock farming, food technology, and the food industry. Of greatest importance are changes in the meat industry, where meat production has shifted from small-scale slaughterhouses with limited distribution patterns to large facilities that process thousands of pigs each day and distribute their products nationally and internationally. Farm sizes have increased and animal husbandry methods have also become more intensive. While many modern slaughter techniques reduce the risk of meat contamination, opportunities for animal-to-animal transmission of the organism, and for cross-contamination of carcasses and meat products, exist on a scale that was unthinkable decades ago. In addition, advances in packaging and refrigeration now allow industry and consumers to store foods for much longer periods, a significant factor with regard to a cold-adapted pathogen such as *Y. enterocolitica*.

A Proper Understanding of the Epidemiology. Our understanding of the epidemiology of yersiniosis is still incomplete. Worldwide surveillance data show that great changes have occurred over the last two decades. The importance of *Y. enterocolitica* as the cause of a number of clinical syndromes is unclear in many areas of the world. Standardized disease surveillance is needed within and across national boundaries so that data from each location are comparable. Improved screening of stools and other specimens for *Y. enterocolitica* is necessary to further elucidate the epidemiology of the disease.

Diagnosis. The analytical methods available today for the determination of pathogenic *Y. enterocolitica* suffer from limitations such as insufficient selectivity, and, in particular, inadequate differentiation between pathogenic and nonpathogenic strains. These analytical shortcomings hopefully will be solved by the new generation of analytical techniques now being developed.

Recommended Methods of Control. At herd level, the avoidance of the purchase and introduction of animals into herds seems to be a contributing factor to the achievement of a negative carrier status.[222] The incorporation of the plastic bag technique into the slaughtering and dressing procedures by the meat industry would contribute to the prevention of the dissemination of *Y. enterocolitica* and other pathogens that spread via feces.[182] The incidence of human yersiniosis has dropped drastically since the introduction of the plastic bag technique in pig slaughterhouses in Norway and Sweden (National Institute of Public Health, Oslo).[234] HACCP and GMP in pig slaughter should focus on limiting the spread of pathogens such as *Y. enterocolitica*.

50 Less Recognized and Suspected Foodborne Bacterial Pathogens

Michael E. Stiles

50.1 Introduction
50.2 Enterobacteriaceae
  50.2.1 *Citrobacter*
  50.2.2 *Klebsiella*
  50.2.3 *Enterobacter*
  50.2.4 *Hafnia*
  50.2.5 Other *Enterobacteriaceae*
50.3 Spiral bacteria of the human stomach
  50.3.1 *Helicobacter*
  50.3.2 *Arcobacter*
50.4 Sporeforming bacteria
  50.4.1 *Bacillus* species
  50.4.2 *Clostridium* species
50.5 Lactic acid bacteria
  50.5.1 *Streptococcus*
  50.5.2 *Enterococcus*
  50.5.3 Food-associated lactic acid bacteria
  50.5.4 Aerococci and other lactic acid bacteria
  50.5.5 Bifidobacteria
50.6 Human diseases (and related bacteria) transmitted through foods
  50.6.1 Coryneform bacteria
  50.6.2 *Mycobacteriaceae*
50.7 Zoonoses transmitted through foods
  50.7.1 Anthrax
  50.7.2 Brucellosis
  50.7.3 Q Fever
  50.7.4 Leptospirosis
  50.7.5 Erysipelas
  50.7.6 Tularaemia
  50.7.7 Intestinal Spirochetosis
50.8 Concluding remarks

50.1 INTRODUCTION

To separate issues of food spoilage and safety, food microbiologists have relied on a distinction between pathogenic and nonpathogenic bacteria. The microflora of foods can be divided into five categories:

1. established foodborne pathogens
2. suspected and less recognized pathogenic bacteria
3. bacteria that serve as indicators of hygiene and safety
4. bacterial agents of food spoilage
5. bacteria that are generally recognized as safe or as health promoting (probiotic) based on their use in food fermentations or as dietary adjuncts.[212]

Early associations of cases of human illness with foods centered on outbreaks of human and animal diseases such as brucellosis, diphtheria, streptococcal infections, typhoid and paratyphoid fevers, and tuberculosis. Spread of these diseases was commonly associated with foods of animal origin, particularly unpasteurized milk and dairy products and inadequately cooked or uncooked meats and fish.[25] In many parts of the world, public health measures virtually eliminated the hazard of contracting these diseases through foods and, as a result, for many years the incidence of foodborne illness was overlooked and it is still underestimated.

In the 1940s, excluding the bacteria associated with human and animal diseases, those with confirmed involvement in foodborne disease were *Clostridium botulinum*, *Salmonella* species, and *Staphylococcus aureus*.[45] These have increased from 3 to more than 15. Dack[45] listed several suspected foodborne pathogenic bacteria. Over the years some of these organisms "emerged" as foodborne pathogens, but others have remained on the list of suspected pathogens. The first detailed account of *Clostridium perfringens* was published in 1953,[117] but it remained a controversial agent of foodborne illness for 20 years before its mechanism of action was confirmed in the late 1960s. The recognition of foodborne illness due to *Bacillus cereus* was even more protracted. *Vibrio parahaemolyticus* was considered "a Japanese phenomenon" of foodborne illness until 1971 when it became recognized worldwide as a foodborne pathogen. Since the 1970s, different enteropathogenic strains of *Escherichia coli* have taken places of notoriety in foodborne illness. In the 1980s, there were many reports of "new" and "emerging" foodborne pathogens, including *Aeromonas hydrophila*, *Campylobacter jejuni* and *Campylobacter coli*, enterohemorrhagic *Escherichia coli* O157:H7, *Plesiomonas shigelloides*, various *Vibrio* species, and *Yersinia enterocolitica*.

Originally, Koch's postulates were paramount in establishing a causal role of a microorganism in disease; but these postulates cannot be proven for difficult-to-culture or nonculturable bacteria, and reliance must be placed on more sophisticated techniques[57] such as molecular techniques with PCR, DNA hybridization, and representational difference analysis. The 12 preceding chapters of this section of the book are devoted to bacteria associated with foodborne illness. The same range of bacteria was afforded separate attention in Doyle's text *Bacterial Foodborne Pathogens* published in 1989[59] except for the major change in emphasis on enterohemorrhagic *Escherichia coli* (EHEC). Since the review of "Less recognized and presumptive foodborne pathogenic bacteria" in Doyle's text,[212] the most significant development in clinical microbiology has been the change in the concept of infectious disease. In 1980, DuPont and Pickering claimed that "almost any bacterial species is capable of producing intestinal symptoms if swallowed in sufficient numbers,"[63] thereby challenging the distinction between microorganisms involved in food spoilage and food safety. This distinction is challenged further by the important change in understanding that production of disease does not reside solely with the pathogenic and virulence properties of the microorganisms but also with the health status of the host, so that "no hard and fast rule divides the human microbiota into clear-cut categories of harmless commensal organisms and pathogenic species."[126] Even lactic acid bacteria used in food fermentations have been cited as "potential pathogens."[105,217] In almost every case of one of these bacteria causing infection, there was a history of underlying disease and (or) vancomycin treatment or oral surgery.[2,87] This led Aguirre and Collins to conclude that some lactic acid bacteria are opportunistic pathogens.[2] Even this statement is speculative because conditions for this behavior, including distinguishing physiological features, must still be defined.

This conceptual change by clinical microbiologists presents a major challenge for food microbiologists, especially for safety of chill-stored and fermented foods in which large numbers of viable bacteria may be present at the time of consumption. The fact that some organisms may be facultative pathogens, depending on factors such as the virulence of the strain, the number of organisms ingested, or the susceptibility of the individual ingesting the organisms, makes a review of less recognized or suspected foodborne pathogenic bacteria more challenging. The bacteria considered in this chapter were selected for inclusion if:

- they represent "emerging" agents of foodborne disease
- they have been implicated in gastroenteritis and other human diseases, and food could serve as the vehicle for transmission
- they were recognized disease agents for which food may serve as the vehicle of transmission
- they were traditionally suspected as agents of foodborne illness but their role in disease has yet to be established.

The review takes into consideration not only the pathogens affecting the healthy population, but also those affecting the population considered to be "at risk," such as infants, young children, and the debilitated (ie, aged, hospitalized, and immunocompromised individuals).

50.2 ENTEROBACTERIACEAE

The family Enterobacteriaceae includes a large number of Gram-negative, facultatively anaerobic, rod-shaped bacteria that are motile or nonmotile and that ferment glucose, often with gas production. The name for the family was derived from *enterobacterium*, meaning an intestinal bacterium. This family is important because of the involvement of many species and strains in human and animal health. They are commonly referred to as "enteric bacteria," but this gives a restrictive impression of their distribution. They are found in soil and water, on plants, and in human and animal intestines.[74] Members of this family are important in food microbiology because they include: intestinal pathogens; the most widely used indicators of hygiene, sanitation, and food safety; and they can be important agents of food spoilage. Until the 1940s, the only recognized gastrointestinal food- or waterborne pathogens in this family were *Salmonella* spp., *Arizona hinshawii* (*Salmonella arizonae*), and *Shigella* spp. Subsequently, enteropathogenic and enterotoxigenic types of *Escherichia coli* and *Yersinia enterocolitica* have been included as gastrointestinal pathogens.[96] Based on phylogenetic criteria, *Salmonella*, *Shigella*, and *E. coli* could be included in one genus,[198] but they have been kept separate for clinical reasons. The "coliform bacteria" are lactose-fermenting members of the Enterobacteriaceae, and include *E. coli*, *Citrobacter freundii*, *Klebsiella pneumoniae*, and some aerogenic *Enterobacter* species such as *E. aerogenes* and *E. cloacae*. Coliform bacteria are used as indicators of hygiene and sanitation during food processing and preparation. Many foods have "acceptable" standards for coliform bacteria. Until the 1970s, the food industry regarded *E. coli* as an innocuous indicator organism. Since then, different strains of *E. coli* have been associated with different virulence genes that have resulted in their association with an alarming array of diseases, including diarrhea, dysentery, hemorrhagic colitis, and hemolytic-uraemic syndrome (HUS), urogenitary tract infections, septicemia, pneumonia, and meningitis.[198]

In *E. coli* it is the virulence genes that make the pathogen. The five virulence types involved in enteropathogenicity of *E. coli* for humans are described in Chapter 43. Enterotoxigenic (ETEC) strains cause diarrheal illness in all age groups by elaborating cholera-like heat labile (LT-I and LT-II) and heat stable (STa and STb) enterotoxins and colonization factor antigens (CFA) I and II that enable the bacteria to adhere in the proximal small intestine. Many ETEC strains produce both CFAs, but some do not produce either, suggesting that other adherence factors can be involved. Genes for LT-I and STa are plasmid-mediated, often on the same plasmid as CFA genes. EHEC strains produce a shiga-like toxin (SLT) and cause a disease similar to shigellosis. The gene encoding SLT is on a temperate phage that could facilitate its transfer to other strains. Enteroinvasive strains cause a disease identical to shigellosis by actively invading epithelial cells of the colon, followed by cell-to-cell spread, but apparently without complications of HUS.

Members of Enterobacteriaceae not normally associated with diarrhea are referred to as "nonpathogens." This is misleading because many strains are implicated in extraintestinal disease. They may be more appropriately referred to as "opportunistic pathogens." They are a major cause of nosocomial infections that are associated with significant morbidity and mortality. Other species isolated from clinical specimens and occasionally associated with intestinal infections include *Citrobacter freundii*, *Citrobacter amalonaticus*, *Edwardsiella tarda*, and species of *Hafnia*, *Kluyvera*, *Morganella*, and *Providencia*.[77,90] Plasmid-mediated virulence traits, the relationship of their toxins to those of *Vibrio cholerae*, and their detection in other Enterobacteriaceae suggest the possibility that other genera and species also could be enteropathogenic. The organisms considered in more detail below are those suspected of being causative agents of gastroenteritis, and may be foodborne.

50.2.1 *Citrobacter*

The genus *Citrobacter* was proposed in 1932 for those "coli-aerogenes" intermediates that use citrate as the sole source of carbon. The type strain *Citrobacter freundii* is biochemically related to *Salmonella* spp., and some strains agglutinate the *Salmonella* polyvalent O antiserum. In addition to *Citrobacter koseri* (synonyms, *Citrobacter diversus* and *Levinea malonatica*) and *Citrobacter amalonaticus* (synonym, *Levinea amalonatica*), five new species and three unnamed species based on genotypic differences have been proposed.[21] *C. freundii* is a normal inhabitant of the human gastrointestinal tract, but all species of *Citrobacter* are considered to be opportunistic human pathogens. The incidence of *Citrobacter* spp. detected in the intestinal tract increases with the occurrence of diarrhea.[7,81] Early studies implicated *Citrobacter* spp. as a probable cause of diarrhea that could sometimes be traced to food handlers, but the evidence was not conclusive. *Citrobacter* spp. are found in many foods, including meat, freshwater fish, and spices.[11,200,202] Enterotoxigenic *C. freundii* may cause diarrhea, and some outbreaks have been foodborne.[77,204] Both *C. diversus* and *C. amalonaticus* cause human infection, but they are not commonly associated with diarrhea. However, in most countries, stool specimens are not routinely examined for *Citrobacter* spp., and there are no well-developed systematic procedures for selective isolation of *Citrobacter* spp. from clinical and environmental samples.[83] Isolation depends therefore on their detection from non-differentiating plating media and identification by biotyping. Simmons' citrate agar can be used as a selective medium to exclude organisms such as *E. coli*, but it does not eliminate other citrate-positive organisms. The organisms are widely distributed in soil, water, sewage, food, and in the gastrointestinal tract of humans and animals as normal inhabitants.[83]

Strains of *C. freundii* have been found that produce ST and LT toxins with high homology to cholera and *E. coli* toxins; however, there was no accumulation of fluid when these strains were tested in the rabbit ileal loop test.[132] In a separate study,[103] *C. freundii* producing STa was detected in strains isolated from children with diarrhea. Strains of *C. freundii* from beef samples and stool samples of patients with diarrhea were shown to harbor SLT-II-related genes.[202] The strains were shown to have moderate cytotoxicity and the results of the study illustrated the intergeneric occurrence of SLT-II toxins. Diarrhea due to *Citrobacter* spp. is not common and, similar to *E. coli,* strains may become pathogenic by acquiring plasmids for enterotoxin production, colonization factors, or other pathogenic mechanisms. In 1973, Sedlák[204] reviewed the genus *Citrobacter* and cited five outbreaks with up to four cases of foodborne illness in each outbreak. Meat products were implicated in two of the outbreaks; milk in another. The organisms were described as being "conditionally pathogenic bacteria." In 1995, an outbreak of severe gastroenteritis with cases of HUS occurred in a nursery school and kindergarten in Germany.[223] Verotoxigenic *C. freundii* on parsley used to prepare green butter for sandwiches was implicated as the cause of infection. The parsley had been fertilized with pig manure. Identical strains of *C. freundii* were isolated from the infected children and the parsley.[223]

50.2.2 *Klebsiella*

Klebsiella pneumoniae is an opportunistic pathogen of humans and animals. With the acquisition of antibiotic resistance, *K. pneumoniae* has become an important nosocomial pathogen.[90] It is present in the gastrointestinal tract of humans and animals, but in lower numbers than *E. coli,* so that enrichment and selective strategies are required to detect them. Environmental isolates are considered to be as "pathogenic" as human and animal strains.[14] The same applies to "fecal" and "nonfecal" isolates. DNA hybridization studies of clinical and nonclinical *Klebsiella* strains[240] indicated three groupings: *K. pneumoniae sensu lato* that includes clinical isolates and relates to a fecal coliform-positive reference organism; other *Klebsiella* "species" that include isolates of nonclinical origin and relate to a nonfecal coliform reference organism; and indole-producing *Klebsiella oxytoca* that are found in both environments. This indicates that fecal-type klebsiellae and *K. oxytoca* are most commonly associated with pathogenicity. Most *Klebsiella* spp. associated with disease and sewage are "fecal coliforms," based on their ability to grow and produce gas at elevated incubation temperatures.[13] The extent to which humans carry *Klebsiella* spp. in their intestines is not clear, but human colonization is considered a major reservoir of *K. pneumoniae* and a step toward infection.[170] Colonization requires doses in excess of 10^8 organisms for some individuals.[170] Person-to-person spread is the most common mode of transmission of *Klebsiella* spp. in hospital infections,[127] but foods have been implicated in intestinal colonization.[171] *Klebsiella* spp. can affect humans of all ages, but infants, the elderly, and immunocompromised individuals are at greatest risk.[114]

Both *K. pneumoniae* and *K. oxytoca* have been implicated in outbreaks of diarrhea.[77,143] Some strains of *K. pneumoniae* isolated from feces of people with diarrhea are enterotoxigenic, and strains that produce LT enterotoxin have been implicated in outbreaks of foodborne illness in Sweden, in which watery diarrhea was the dominant symptom.[47] ST enterotoxin produced by *K. pneumoniae* has been purified and it has cross-reactivity with, and the same potency as, *E. coli* ST enterotoxin in the suckling mouse assay.[142] The transfer of CFA/I gene from *E. coli* can occur, producing a functional adherence factor for the pathogenicity of *Klebsiella*.[243] Virulence of *K. pneumoniae* is influenced by adherence mechanisms that promote attachment of the bacteria to the epithelial cells and enable the organism to overcome the host defense mechanisms.[114] The presence of a cell capsule also is involved in virulence of *K. pneumoniae* acting to protect the cell from phagocytosis.[56,114]

K. pneumoniae has been isolated from meats, milk and dairy products, fresh vegetables and fruits, soil, dust, air and water, the hospital environment, industrial effluents, and environments not associated with fecal contamination.[13,101,170,171,197] *K. pneumoniae* was isolated from 53 of 115 vegetable salads prepared in a hospital, with counts in 37 of the salads between 10^3 and 10^6 cfu g^{-1} (colony-forming units per gram).[241] Samples of high-calorie milkshakes contained 10^3 to 10^6 ml^{-1} *K. pneumoniae*;[171] the source of contamination was traced to the milkshake mixer. *K. pneumoniae* can grow in Mozzarella cheese with only moderate temperature abuse.[160] The organism has also been reported as a pathogen of freshwater fish.[11] Its ability to produce enterotoxins and its isolation from many foods suggest a role for *K. pneumoniae* in foodborne illness.[143,170]

Foodborne outbreaks of gastroenteritis due to *K. pneumoniae* may not be reported because the organism is not considered seriously as a cause of foodborne illness in normal healthy individuals, nor has it been systematically sought as a foodborne enteropathogen. An outbreak of foodborne illness attributed to *Klebsiella* spp. was described by Horváth et al.[119] A total of 190 people became ill. Symptoms of foodborne illness appeared 10 to 15 hours after a common meal was eaten. The symptoms included headache, dizziness, vomiting, and watery diarrhea accompanied by severe cramps. There were no reports of fever, and recovery occurred in 6 to 8 hours. *Klebsiella* spp. were isolated from stool specimens, and 10^6 to 10^7 cells g^{-1} were isolated from some of the foods. Unfortunately, the isolates were not serotyped and other potential pathogens also were isolated in relatively low numbers from some of the foods. Studies in Mexico led Mesta et al.[168] to conclude that *K. pneumoniae* is a primary cause of gastroenteritis of uncompromised hosts. *K. pneumoniae* was cited by Madden et al. as an agent of foodborne illness in their review of virulence assessment of foodborne microbes.[155]

50.2.3 *Enterobacter*

The genus *Enterobacter* was recognized in the 1970s, and eight species are now distinguished.[77] *E. cloacae* and *E. aerogenes* are established species of this genus, and *E. cloacae* is the type species. *Enterobacter agglomerans* is a heterogeneous species that has been moved to a new genus, *Pantoea*.[88] There are no isolation media that are specific for *Enterobacter*. The genus is a large, heterogeneous group of organisms that are differentiated from one another and from *K. pneumoniae* by their lysine- and ornithine decarboxylase and arginine dihydrolase activities, as well as motility.[99,136] *Enterobacter* spp. normally exist as saprophytes in the gastrointestinal tract of humans and animals. They also are widely distributed in nature, in water, sewage and soil, on plants and in foods—notably dairy products, meats, vegetable salads, and spices[96,200,241]—and infant formula.[154,189] Although they are enteric bacteria, they are seldom reported as enteric pathogens; however, they are opportunistic pathogens that cause extraenteral infections, generally of nosocomial origin.[99,136] The incidence of *E. cloacae* in human infections is greater than that of *E. aerogenes*, but *E. aerogenes* might have been misidentified as *K. pneumoniae* or *E. cloacae* in earlier studies.[99] *E. sakazakii* (previously, yellow pigmented *E. cloacae*) is usually a commensal of the human intestine, but it has occasionally been isolated as an extraenteral pathogen.[99] It was also isolated from powdered milk[75] where it was reported to cause foodborne illness of infants in a hospital setting where the infection was caused by cross-contamination and temperature abuse.[178,189] The thermal resistance of *E. sakazakii* appears to be higher than that of many other Enterobacteriaceae.[177]

There were a few early reports of the "cloacae-aerogenes" group in foodborne diarrhea, but these were not substantiated. *E. cloacae* has been isolated from the small intestine of people with acute diarrhea.[143] An *E. cloacae* isolate that caused fluid secretion in a rabbit ileal loop test elaborated ST enterotoxin comparable to that from strains of *E. coli* and *K. pneumoniae*.[141] *Enterobacter* spp., especially *E. cloacae* and *E. sakazakii*, should be viewed as potential agents of foodborne illness, but more epidemiological information on these organisms is required to allow a more reliable assessment of their potential as foodborne pathogens.

50.2.4 *Hafnia*

The organism previously known as *Enterobacter hafniae* or *Enterobacter alvei* was reclassified as *Hafnia alvei*.[197] The role of *H. alvei* in gastroenteritis has been controversial, but epidemiologic evidence indicates an association between strains of *H. alvei* and diarrhea.[3,192] *H. alvei* also has been associated with extraintestinal infections, usually in patients with underlying illness; however, most *H. alvei* strains are not considered to be pathogenic for humans.[104] No special media have been developed to enrich or isolate *H. alvei*. The organism grows well on desoxycholate-lactose-sucrose-sorbitol agar.[197] It may not grow well on media typically used to isolate salmonellae, but when it does, it can resemble *Salmonella* because it does not ferment lactose. *H. alvei* generally grows well in selenite and tetrathionate broths, and its biochemical reactions are close to those of *Enterobacter* and *Serratia*.[197]

50.2.5 Other Enterobacteriaceae

Edwardsiella tarda is a well-recognized cause of extraintestinal infections in humans, but it is also considered to be a possible cause of diarrhea,[35,136,203] especially in developing countries.[196] *E. tarda* is found rarely in the feces of healthy people, but a higher isolation rate has been found among patients with diarrhea.[92] The possibility that *E. tarda* is involved in the pathogenesis of amoebic dysentery has been suggested.[92] Heat-stable enterotoxin was detected in *E. tarda* isolates.[19] Because *E. tarda* would be expected to have an enteroinvasive pathogenesis, the role of ST enterotoxin is not clear. *E. tarda* has been isolated from cold-blooded animals, which may serve as a reservoir for human infection.[196] However, the association of *E. tarda* with diarrhea does not necessarily indicate a causal relationship,[92] and food is considered an unlikely vehicle for this organism. *Kluyvera* spp. are normally regarded as saprophytes; however, they have been isolated from cancer patients and from a healthy subject with diarrhea.[72] Based on the fact that *Kluyvera* spp. can colonize the intestinal tract and they are found in food, these organisms have the potential to cause diarrhea that is foodborne in origin. It has not yet been shown that *Kluyvera* spp. cause gastroenteritis or foodborne illness.

Proteus, *Providencia*, and *Morganella* are differentiated from other members of Enterobacteriaceae by their oxidative deamination of a wide range of amino acids. Members of the *Proteus* group have long been recognized by bacteriologists because they swarm on the surface of agar media, produce a characteristic odor, and cause off-odors and spoilage of foods. Swarming is not a characteristic limited to these bacteria; in fact, it has been associated with *Salmonella* that are exceptionally virulent.[90] The genus *Proteus* has long been suspected as an agent of foodborne illness.[45] In eastern Europe investigators reported outbreaks of foodborne illness due to *Proteus* based on large numbers of organisms in implicated foods and in stools of patients with gastroenteritis.[7] The genus *Morganella* contains the organism previously known as *Proteus morganii*.[77] It was originally isolated from infants with diarrhea, and it has subsequently been implicated as a cause of diarrhea.[187] It is included with those bacteria responsible for causing histamine poisoning associated with eating fish of the suborder Scombroidea (tuna, mackerel, and bonito). These fish contain high levels of histidine, which is decarboxylated by the bacteria to histamine, saurine, and related products. The genus *Providencia* includes pathogens of the urinary tract,[77,187] for which fecal colonization serves as a potential reservoir.[113] *Providencia alcalifaciens* (previously *Proteus inconstans* biogroup A) has become a noted infectious agent of humans, particularly of the gastrointestinal tract,[187] but its causative role in gastroenteritis has not been proven.[77] Higher frequencies of isolation of *Providencia* from patients with diarrhea than for healthy persons have been reported.[7] The habitat of *Providencia* includes decaying organic matter, polluted water, soil, manure, and feces.[187] The genus *Proteus* is commonly isolated from the human intestine, and the intestine is considered a potential reservoir for infection, especially in hospitalized patients. *Moellerella wisconsensis* was isolated from feces and, in one notable instance, was implicated in a severe case of bloody diarrhea, fever, abdominal pain, and cramps contracted during overseas travel.[77] There is no evidence that *M. wisconsensis* actually causes diarrhea, but the same applies to members of the tribe *Proteeae* in general. There is no evidence that this group of bacteria has a role in foodborne illness; however, they are clinically important bacteria, primarily causing severe urinary tract infections, and because of the extreme antibiotic resistance of some strains.[187]

In the eighth edition of *Bergey's Manual*, the genus *Serratia* consisted of one species, *Serratia marcescens*. Since then, *Enterobacter liquefaciens* has been reclassified as *Serratia liquefaciens* and six other species have been added, including the atypical species *Serratia fonticola*.[77] *S. liquefaciens* occurs among the psychrotrophic microflora of meat, milk, and vegetable salads.[131,214,241] In recent years, *Serratia* have been added to the list of Enterobacteriaceae that potentially are pathogenic for humans. *S. marcescens* is recognized as a frequent cause of severe extraintestinal infections, particularly nosocomial infections.[76] At this time, available evidence does not implicate *Serratia* species as gastrointestinal pathogens or as pathogenic agents of foodborne origin;[100] however, in a study of enterotoxigenic bacteria isolated from foods, LT enterotoxin-producing strains of *S. liquefaciens* and *Serratia rubidaea* were reported.[129]

50.3 SPIRAL BACTERIA OF THE HUMAN STOMACH

Spiral-shaped bacteria traditionally were associated with the family Vibrionaceae that included four genera, of which *Aeromonas*, *Plesiomonas*, and *Vibrio* contained species associated with foodborne disease. The genus *Vibrio* still contains more than 25 species, many of which have been implicated as human and animal pathogens—especially *Vibrio cholerae*, *Vibrio parahaemolyticus*, and *Vibrio vulnificus* (Chapter 48). The group of bacteria that were known as "related vibrios" and associated with diarrhea in humans became part of the new genus *Campylobacter* and included the intestinal pathogens *Campylobacter jejuni* and *Campylobacter coli* (Chapter 40). Transmission of *C. jejuni* to humans has occurred through contaminated water, unpasteurized or recontaminated pasteurized milk, and undercooked meats, especially poultry.[233] *C. jejuni* also is transmitted to humans from pets. The genera *Campylobacter* and *Arcobacter* were proposed as the family *Campylobacteriaceae.*[176] These organisms are biochemically inert, resulting in generalized groupings such as gastric campylobacter-like organisms and urease-positive thermophilic campylobacters. The genus *Campylobacter* became a depository for varied groups of organisms. Many other species (groups) of *Campylobacter* have been described, including *Campylobacter pylori* and aerotolerant campylobacter-like strains. These became the genera *Helicobacter* and *Arcobacter*, respectively, and the family *Proteobacteria* has been described to include *Arcobacter, Campylobacter,* and *Helicobacter.*[226]

50.3.1 *Helicobacter*

Spirochetes and spirillum-shaped bacteria have been associated for many years with the stomachs of humans and animals. From the beginning of the 20th century, spiral-shaped bacteria were reported in patients with gastric cancer and peptic ulcer disease.[61] Based on 16S rRNA gene sequence analysis, the new genus *Helicobacter* was proposed, which is closely related to the genera *Campylobacter, Flexispira,* and *Wolinella*. The genus *Helicobacter* is widely distributed as intestinal bacteria in different animals. *H. pylori* is the most common cause of chronic active gastritis, and *H. fennelliae, H. cinaedi,* and *Flexispira rappini* are associated with enteritis.[94]

H. pylori is morphologically similar to *C. jejuni*, hence it was originally classified as the "pyloric campylobacter" and subsequently as *C. pyloridis* and *C. pylori.* Despite reports over a period of 20 years that campylobacter-like bacteria are associated with gastritis and gastric and duodenal ulcers, the possibility that peptic ulcer or gastric cancer might be associated with an infectious agent was discounted.[156,157] However, by 1994 a conference of the US National Institutes of Health presented a consensus regarding the role of *H. pylori* in gastric and duodenal ulcers.[180] *H. pylori* had been associated also with the chain of events leading to adenocarcinoma and lymphoma of the stomach.[61] The Consensus Conference noted that "virtually all *H. pylori*-positive patients demonstrate antral gastritis" but only a small proportion of individuals harboring the organism develop ulcers. They concluded that recurrence of duodenal ulcer can be prevented by elimination of *H. pylori* from the stomach and duodenum, but that the relationship between *H. pylori* and gastric cancer requires further study.[180] People infected with *H. pylori* have an increased risk of developing gastric adenocarcinoma and lymphoma.[180]

H. pylori is a Gram-negative, microaerophilic, motile, spiral-shaped bacterium with one to six polar flagella. An infective but nonculturable coccoid phase that reverts to the viable form has been reported.[233] *H. pylori* colonizes the nonacid-secreting mucosa of the stomach. It is considered to be a pathogen because its presence is associated with chronic active gastritis and its eradication results in resolution of the gastritis. It is present in 95% of duodenal ulcers and in 70% to 80% of gastric ulcers, but whether or not it is a frank or opportunistic pathogen is not clear.[94] Most infections are without clinical consequence and family members of patients may be asymptomatic carriers. Studies of seropositivity indicate that *H. pylori* is distributed widely and is related to socioeconomic status. Risk factors associated with gastritis include smoking, alcoholism, immunosuppression associated with HIV, and consumption of salty, smoked, or pickled foods.[18] In 1996, Wesley reviewed the risk of contracting *Helicobacter* and *Arcobacter* through foods and beverages.[233] The information is not definitive, but it appears that these infections can occur by the fecal-oral route, person-to-person through saliva, pet-to-human, and from ingestion of foods and beverages; whereas Harris and Misiewicz[106] noted that *H. pylori* has not been isolated from the environment or animal sources and they do not cite food as a possible source of infection. In any event, appropriate preparation of cooked foods should kill contaminating bacteria.

50.3.2 *Arcobacter*

Arcobacter was originally described as an aerotolerant campylobacter, *C. cryaerophila.* Aerotolerance, growth at 15° C and optimum growth at 30° C, failure to produce H_2S, and growth in the presence of 2.5% NaCl distinguish *Arcobacter* from *Campylobacter* spp.[244] *Arcobacter* infections in humans are associated with gastroenteritis. Three species have been implicated: primarily *A. butzleri*, and also *A. cryaerophilus* and *A. skirrowii.* The transmission of *A. butzleri* is associated with consumption of contaminated water or food and also person-to-person contact. The association of *A. butzleri* with pork and poultry is strongly indicated.[37,244] *Arcobacter* infections of animals are associated with abortion and enteritis, but only enteritis has been reported for human infections.

50.4 SPOREFORMING BACTERIA

The endospore-forming bacteria, primarily of the genera *Bacillus* and *Clostridium*, survive in nonsterile foods because of the resistance of spores to heat and other adverse environmental conditions. This is well-recognized in the role of *Bacillus cereus*, *Clostridium botulinum*, and *Clostridium perfringens* in foodborne illness reviewed in Chapters 39, 41, and 42, respectively.

Diarrheal illness caused by foodborne bacilli was reported early in the 1900s but the causative organisms were described as belonging to the "subtilis-mesentericus group" or called "pseudoanthrax or anthracoid bacilli." In 1948, Hauge established that it was *Bacillus cereus* that caused an outbreak of foodborne disease in Norway.[112] Nonetheless, except for *Bacillus anthracis*, members of the genus *Bacillus* were generally considered nonpathogenic until the 1960s. The genus *Clostridium* has been more traditionally associated with pathogenicity.[5] These organisms are ubiquitous, occurring in air, soil, water, feces, milk, and other foods. *Bacillus* species are facultative anaerobes, generally catalase-positive and motile; *Clostridium* species are generally obligate anaerobes and catalase-negative, and they are either fermentative or proteolytic, or both.

50.4.1 *Bacillus* Species

Despite the marked difference in significance of *Bacillus anthracis* compared with other *Bacillus* spp., it is closely related to *B. cereus*, *B. cereus* var. *mycoides*, and *B. thuringiensis*;[195] however, avirulent strains of *B. anthracis* clearly are identifiable as anthrax bacilli and not *B. cereus*.[29] *B. cereus* and *Bacillus subtilis* emerged as causative agents of foodborne illness (see Chapter 39) and as clinical and veterinary pathogens.[147] *Bacillus brevis* and *Bacillus licheniformis* are suspected as possible agents of foodborne illness. Other *Bacillus* spp. have less epidemiological evidence to implicate them as causes of foodborne illness, but their repeated occurrence in foods associated with foodborne illness has created suspicion about their involvement.[147] The symptoms of foodborne illness attributed to the less recognized *Bacillus* spp. include vomiting and diarrhea, and in some cases abdominal cramps, nausea, and pyrexia.[147] Some exceptionally short incubation periods (15 to 30 minutes) have been reported, but in general, others range from 1.5 to 10 hours. In outbreaks of foodborne illness attributed to the other *Bacillus* spp., a notable feature is the presence of the organism at high levels ($>10^6$ cfu g^{-1}) and in almost pure culture.[147,222] Suspected foods include meats, pizza, and whole meal bread.[147,222]

B. licheniformis has been implicated in incidents of foodborne illness with symptoms similar to those of *C. perfringens* food poisoning.[147] The time for onset of symptoms was 4 to 15 hours. Foods implicated were cooked meat dishes that contained *B. licheniformis* at 10^5 to 10^9 cfu g^{-1}.[128,147] *B. brevis* has been isolated from suspected foods in outbreaks of foodborne illness. The organism has been isolated also from a patient's feces.[89,147] An outbreak of *B. brevis* food poisoning was reported in 1984.[232] The mean incubation time was 4 hours and symptoms included nausea, vomiting, and abdominal discomfort. A heat-labile enterotoxin produced by the strain of *B. brevis* was responsible. There do not appear to be any special circumstances that differentiate the control of these *Bacillus* spp. from those for *B. cereus*.

50.4.2 *Clostridium* Species

Clostridium perfringens type C is a common pathogen of animals, especially young animals because of the poorly developed intestinal microflora. In humans, this organism causes a rare but severe necrotizing disease of the small bowel known as "enteritis necroticans" or "pig-bel." The possible involvement of *C. perfringens* type C in neonatal necrotizing enteritis has increased the interest in this organism.[140] A classic report of *C. perfringens* type C enteritis necroticans was written by Murrell and coworkers.[175] The disease was associated with ceremonial pig feasts in Papua, New Guinea. The organism is either part of the normal intestinal flora, or it is ingested with contaminated pork during a pig feast. Several factors are involved in the pathogenesis of this disease: overeating, poor level of nutrition, and a diet rich in trypsin inhibitors.[228] The organism proliferates in the small intestine and produces b-toxin. The toxin causes inflammation, hemorrhage, and gangrenous necrosis of the intestine.[5] The disease was reported also in Germany after World War II, where it was known as *darmbrand*, literally meaning "burning intestine."[245]

Neonatal necrotizing enterocolitis is a closely related disease, with varied causes that may include *C. perfringens* types A and C[229] and *Clostridium butyricum*.[122] Most infants who developed this disease were fed cow's milk formula rather than breast milk.[145] A case of necrotizing enterocolitis in a full-term infant was attributed to feeding concentrated formula instead of a "ready-to-feed" formula.[179] The pathogenesis of clostridial necrotizing enterocolitis has yet to be clarified;[146] however, it is hypothesized that in the neonate the disease occurs by coincidence of two of three pathological events: deficiency of blood supply to the intestine (intestinal ischaemia), colonization by pathogenic bacteria, and excess protein substrate in the intestine.[145]

Clostridium difficile is a highly infectious organism that has been implicated as a major cause (50% to 95%) of antibiotic-associated diarrhea and 20% of cases of pseudo-membranous colitis (necrotizing enterocolitis).[5,9,80] Transmission is primarily by hands of hospital workers and not by food or other environmental sources;[80] nonetheless, the diseases are considered here for their potential food or diet association. *C. difficile* may be a normal constituent of the fecal flora of healthy infants;[65] it is rare and transient in the intestine of the healthy adult[9] and it has been isolated from marine sediments, soil, hospital environment, and animal feces.[208] *C. difficile* is nonhemolytic and nonproteolytic, and it produces a wide range of fermentation products. Most strains are toxigenic, producing an enterotoxin (toxin A) and a cytotoxin (toxin B).[5] Diagnosis depends on detecting either the toxin(s) or the organism in stools, or by antibody assay.[9] Symptoms vary from serious, sometimes lethal, bloody diarrhea indicative of colitis to self-limiting, watery stools.[9] Pseudomembranous colitis occurs mainly as a result of the disruption of the normal ecology of the gastrointestinal tract caused by antibiotic therapy or drastic dietary change. *C. difficile* may be naturally present in the intestinal flora and elimination of the competing microflora allows it to grow and produce entero- and cytotoxins.[216] This organism has emerged as an important cause of mild to severe gastroenteritis, but it appears unlikely, at this time, that food plays a role in the transmission or spread of the disease. The literature on this organism and its pathogenesis is expanding rapidly.[80]

50.5 LACTIC ACID BACTERIA

Lactic acid bacteria are a loosely defined group of coccus- and rod-shaped, Gram-positive, catalase-negative bacteria that produce lactic acid as the principal end product of growth. Many of the lactic acid bacteria are commonly found in foods and used in food fermentations. The lactic acid bacteria include the genera *Aerococcus*, *Enterococcus*, and *Streptococcus*, which contain species that are frank pathogens. Phylogenetically, the lactic acid bacteria belong to the clostridial branch of the Gram-positive bacteria. They have a guanidine plus cytosine (G+C) content of their DNA that generally is less than 50 mol%. Lactic acid bacteria used as starter cultures in fermented foods or that grow as the adventitious microflora of foods are considered innocuous, in some cases, even advantageous for human health (probiotic). Lactic acid bacteria are also common commensals of the indigenous microflora of the intestinal tract and mucous membranes of humans and animals.

50.5.1 *Streptococcus*

The original genus *Streptococcus* included a wide range of bacteria. Some species produce specific carbohydrate antigens (C substances) in the cell wall, which formed the basis of the Lancefield classification system. Based on DNA homology studies, the genus was separated into three genetically distinct groups: *Streptococcus sensu stricto*, *Enterococcus*, and *Lactococcus*.[201] The species remaining in the genus *Streptococcus* include the pathogens *S. pyogenes*, *S. pneumoniae*, and *S. agalactiae*; the oral streptococci (or Sherman's Viridans group); and the nonpathogenic starter organism *S. thermophilus*. The pathogenic streptococci are β-hemolytic. *S. pyogenes* has re-emerged as a serious human pathogen with involvement in toxic shock syndrome and necrotizing fasciitis, though it appears that there may not be an increase in real incidence or severity of infections. The route of infection is from localized trauma and not from symptomatic pharyngitis; therefore, it is not likely to be from foods.[211] Streptococci can be transmitted through foods by an infected worker handling ready-to-eat foods. Before the widespread use of pasteurization and refrigeration of milk, there were frequent milkborne outbreaks of scarlet fever and septic sore throat caused by group A streptococci. Meat handling also was implicated as a means of transmission. Foodborne outbreaks were characterized by their "explosive nature." More recent outbreaks have implicated a range of prepared, ready-to-eat foods, such as egg, potato, and shrimp salads, mousse desserts, and a rice dressing.[51,159]

Closely related β-hemolytic groups B and C streptococci have been implicated also in foodborne disease, despite the fact that they may be primarily animal pathogens. *S. agalactiae* (group B) is a principal cause of bovine mastitis and a bacterial pathogen in newborn infants. Group B streptococci are found in 25% of genital and gastrointestinal tracts of human adults, and they are often carried pharyngeally.[70] The most likely source of neonatal *S. agalactiae* infections is the natural microflora of the urogenital tract. This organism only rarely has been associated with foodborne outbreaks of diarrhea; for example, breast milk fed to infants,[181] which suggests a need for extreme care in human milk banking. *Streptococcus zooepidemicus* has been implicated in outbreaks of human pharyngitis, followed by a nephritic sequela.[15,70] These outbreaks were attributed to consumption of unpasteurized milk and Queso Blanco cheese made from raw cow's milk. Group F streptococci are not widely recognized as human pathogens because they seldom infect healthy individuals, and infections are usually associated with underlying disease. However, they have been implicated in severe infections and they are unique among the streptococci for their involvement in abscess formation. Their mode of transmission is not clear, but the gastrointestinal tract is the most likely source of infection.[152] β-haemolytic group G streptococci are part of the normal microflora of the skin, pharynx, gastrointestinal tract, and vagina. They are important opportunistic pathogens, causing serious infections. The most common portal of entry is the skin, and pharyngeal colonization is common, but foodborne outbreaks have been reported. Group G streptococcal pharyngitis reported in two foodborne outbreaks resembled group A streptococcal pharyngitis, but without the group A sequelae.[10,149] In one outbreak, an egg salad was incriminated as the vehicle of infection;[115] in the other outbreak, a chicken salad was suspected, and after the outbreak a cook was found to be positive for group G streptococci.[215]

50.5.2 *Enterococcus*

The enterococci have been recognized since Thiercelin in 1889[221] described them as the "entérocoque" to emphasize their intestinal origin; in 1906, Andrewes and Horder[6] used the name *Streptococcus faecalis* for the enterococcus-type organism that was isolated from a patient with endocarditis. The taxonomy of this group of bacteria has been vague. In 1937 the enterococci were described by Sherman[205] as those organisms that grow in broth containing 6.5% NaCl at 10° C to 45° C, grow at pH 9.6, survive heating at 60° C for 30 minutes, and react with Lancefield group D antisera. Many species and strains of the genus *Enterococcus* do not meet all of these criteria. Sherman[205] also suggested that the enterococci could be differentiated on the basis of their hemolytic and proteolytic reactions; however, hemolysis is plasmid-mediated[124] and therefore inappropriate as a characteristic for species differentiation. When the genus *Enterococcus* was separated from *Streptococcus sensu stricto* and *Lactococcus*,[201] it included the Lancefield group D (fecal) streptococci, *E. faecalis* and *E. faecium*, but not *Streptococcus bovis* or *Streptococcus equinus*. The genus *Enterococcus* forms a cluster with the genera *Carnobacterium*, *Tetragenococcus*, and *Vagococcus*, and it is more closely related to *Listeria* than to *Lactococcus* or *Streptococcus*.[38,55]

The main reservoir for enterococci is the intestinal tract of humans and animals, but the organism also resides in the oral cavity, gall bladder, urethra, and vagina. Enterococci, usually *E. fecalis*, are considered the second most important nosocomial pathogen. *E. faecalis* has inherent resistance to several antibiotics, and it has been identified as a causal agent of human endocarditis, bacteremia, urinary tract, intraabdominal, and soft tissue infections and neonatal sepsis,[151] whereas *E. faecium* is only implicated as the causative agent in 20% of clinical cases due to enterococci.[134,174] Since re-establishing the genus in 1984, 9 species have been transferred from the genus *Streptococcus*, and 10 new species have been added.[55] They frequently are associated with polymicrobial infections of the abdomen and pelvis. Their etiologic significance in these infections is not clear. In developing countries, the enterococci have been associated with infant diarrhea.[67] The importance of the enterococci for food and public health microbiologists is related to their enteral habitat, their use as indicators for food safety, and their possible involvement in foodborne illness.[212] Despite this, enterococci (mainly *E. faecium*) have been studied for a probiotic role in disease prevention and for treatment of intestinal disorders of humans[150] and animals,[225] and they are available commercially.

In food microbiology it was considered important to identify "*Streptococcus durans*" to distinguish between group D streptococci of fecal and nonfecal origin. *S. durans* had a volatile taxonomic history ranging from species to varietal status within the group D streptococci. Based on DNA hybridization studies, it was shown that *E. faecium* consisted of two distinct entities,[79,137] and the "durans" group was proposed as *Enterococcus durans*.[40] It presently is listed as a pathogenic *Enterococcus*. It has been isolated as an intestinal inhabitant of humans and poultry, thus discounting the previously held view that the "durans" variety represents a nonfecal population. *E. durans* was shown to consist of two distinct DNA homology groups. Homology group I has been retained as *E. durans*, while homology group II is highly related to *Enterococcus hirae*, which has been characterized among isolates from chicken and hog intestines.[78] *E. hirae* therefore includes strains of human, bovine, avian, and porcine origin,[144] and is primarily associated with chicken crops and hog intestines. Many of the newly described species of *Enterococcus*, such as *E. durans* and *E. flavescens*, are of clinical origin whereas others, especially the pigmented species, such as *E. mundtii* and *E. casseliflavus*, are primarily of plant origin.[158,188] *E. faecalis* and *E. faecium* are distributed widely in the environment and also have been associated with plants.[158] This means that public health and food microbiologists must exercise caution when interpreting the meaning of enterococci in foods.

There are many reports of enterococci in foods and the food environment. Some researchers believe that enterococci can cause food poisoning,[172] but Bryan[24] considered that "if enterococci are pathogenic, the situation is probably analogous to the association of coliform bacteria with pathogenicity," and that they only become enteropathogenic under special conditions. In instances where the enterococci have been associated with foodborne illness, the symptoms were vague and variable, including nausea, sometimes vomiting, colicky pains, and diarrhea.[52,172] Efforts to prove that the enterococci cause foodborne illness have included studies with human volunteers, but ingestion of various substrates containing large numbers of enterococci or their filtrates gave equivocal results.[24] Some positive tests with human volunteers have been reported, especially with a Vienna sausage containing α-hemolytic streptococci and a broth culture of the same organism, but not from the bacteria-free filtrate.[30] Variable results were reported when 6 of 27 volunteers became ill after consuming different strains of *E. faecalis* grown in foods.[182] Some volunteers ingested more than 1×10^{10} organisms without showing any symptoms. In fact, some of those who did not show symptoms ingested larger doses than those who became ill,[182] showing a marked difference in response between individuals.

Enterococci are commonly isolated from foods. They are more difficult to control in foods than many other bacteria. Not only their presence in the mammalian intestine but also their adaptation to food processing environments, their relative heat resistance, and their growth over a wide temperature range make control difficult. If certain strains are shown to be enteropathogenic, the critical control procedures of rapid chilling of foods below 5° C or holding above 60° C, and reheating of refrigerated foods to > 70° C before serving, will have to be even more strongly emphasized.

50.5.3 Food-Associated Lactic Acid Bacteria

Many lactic acid bacteria are involved in spontaneous fermentations that acidify and preserve foods. A well-developed fermentation industry exists for cheese and other dairy products, fermented sausages and vegetables, and sourdough bread. It is estimated that 25% of the world's foods are fermented, many of which contain large numbers of viable organisms at the time of consumption. The lactic acid bacteria involved in food fermentation include species of the genera *Lactobacillus*, *Lactococcus*, *Leuconostoc*, and *Pediococcus*. All of these bacteria have occasionally been isolated from human infections. This has culminated in reviews of the lactic acid bacteria in human infections by Aguirre and Collins,[2] Gasser,[87] and Facklam and Elliott.[71] Reviews of lactobacilli,[217] leuconostocs,[105] and pediococci[43,161] in human infections concluded that some of these bacteria should be viewed as "potential pathogens." Aguirre and Collins in 1993 and Gasser in 1994 acknowledged the beneficial role of lactic acid bacteria in food preservation and probiotics, but they cited numerous cases in which lactic acid bacteria were implicated in human disease; in particular they noted the importance of enterococci in clinical infection.[2] Gasser[87] questioned why the lactic acid bacteria were being isolated more frequently from clinical cases, whether some lactic acid bacteria are becoming pathogenic, and whether some species or strains contain virulence factors. He concluded that the more sophisticated techniques for identifying bacteria could influence this; furthermore, that fastidious bacteria such as lactic acid bacteria may have been overlooked in the past. There is no evidence that the lactic acid bacteria are becoming pathogenic for healthy adults.

In the case of the lactococci, it is possible that they were misidentified as enterococci because these bacteria are physiologically similar. The lactococci were first implicated in human endocarditis in 1985.[237] Most lactococcal infections are caused by *Lactococcus lactis* subspecies *lactis* and *Lactococcus garvieae.*[64,237] Other lactic acid bacteria involved in cases of endocarditis, apart from the enterococci, are *Lactobacillus rhamnosus* (previously *Lactobacillus casei* subspecies *rhamnosus*), *Lactobacillus plantarum*, and *Lactobacillus casei* or *paracasei.* Nonetheless, in surveys of bacteria implicated in infective endocarditis, the incidence of the lactic acid bacteria is extremely low.[87] The principal lactic acid bacteria associated with primary infections of the blood stream are leuconostocs, but the incidence is also rare; *Lactobacillus* infections of the blood stream generally are secondary, resulting from infection with the same organism at another site in the body.[87] Members of the genus *Pediococcus*, primarily *P. acidilactici*, have been implicated in bacteremia and stomach and hepatic abscesses.[71,161] In most cases of infection with lactic acid bacteria, there was a breakdown in the normal host defenses, associated with conditions such as extremes of age, underlying disease, immunosuppressive therapy, and, in particular, after treatment with vancomycin. Leuconostocs and pediococci are vancomycin-resistant. Up to 30% of leuconostocs react with the group D antiserum, and in the past these infections probably were reported as unidentified enterococci. Despite the widespread distribution of leuconostocs and pediococci in foods, they cause relatively few infections; it is assumed that they have very little virulence for healthy humans.[71]

The newer genera of lactic acid bacteria, *Carnobacterium*, *Oenococcus*, *Tetragenococcus*, and *Weissella* have not been associated with human infections; however, this may simply be due to the relatively short time that these organisms have been known. *Leuconostoc paramesenteroides* (now *Weissella mesenteroides*) has been associated with a few cases of human infection.[71] The carnobacteria were previously described as atypical lactobacilli, but since they have been separated as a new genus, it has been shown that they are more closely associated with enterococci than the lactobacilli.[213] The genus *Tetragenococcus* was derived from *Pediococcus halotolerans.* It is important in the fermentation of soy sauce. It has not been associated with human infections.

50.5.4 Aerococci and Other Lactic Acid Bacteria

The genus *Aerococcus* forms tetrads and contains the species *A. viridans*, known by the synonyms *Gaffkya homari* or *Pediococcus homari*, which causes a fatal disease of lobster.[116] *A. viridans* has been associated also with endocarditis with or without predisposing disease conditions, bacteremia in patients with leukemia, meningitis in children, osteomyelitis, and septic arthritis.[1] *Aerococcus urinae* is an opportunistic pathogen of the urinary tract, primarily among the elderly, especially those with predisposing conditions of diabetes or cancer.[34] The aerococci are widely distributed in nature, in air, water, and soil, hospital environments, plant material, and meat-curing brines;[1] the possible involvement of aerococci in foodborne disease is discussed in Chapter 38.

There are several new genera that have been isolated from clinical sources and that fit the description of lactic acid bacteria; however, their ecological distribution generally is not known. *Gemella* are Gram-variable diplococci and comprise two species: *G. haemolysans* (previously *Neisseria haemolysans*) and *G. morbillorum* (previously *Peptostreptococcus morbillorum*). They are commensals of the mucous membranes of humans and some warm-blooded animals.[16] *G. haemolysans* is commonly found in the intestinal tract of humans. These bacteria are opportunistic pathogens, primarily of immunocompromised individuals. The genus *Globicatella* is closely related to the aerococci, but they form short chains not tetrads. They have been isolated from cases of bacteremia and urinary tract infections. They are a genetically distinct group with closest affinity to the *Aerococcus* phylogenetic branch of the lactic acid bacteria. The closely related genus *Helcococcus* has been isolated from wound infections[39] and *Alloiococcus* from middle ear infections.[71] The genus *Vagococcus* was proposed for the motile lactococci. They are more closely related to the enterococci than to the lactococci. There are two species, *V. fluvialis* and *V. salmoninarum*, but they are rarely associated with clinical infections.[71]

50.5.5 Bifidobacteria

The genus *Bifidobacterium* is no longer considered as one of the lactic acid bacteria because of their relatively high G+C content,[210] but the genus originated from bacteria that were originally classified as *Lactobacillus bifidum.* The bifidobacteria were originally isolated from infant feces and they are currently attracting considerable interest for their role as probiotics. Bifidobacteria have been isolated from polymicrobial infections of children, often with predisposing conditions.[22]

50.6 HUMAN DISEASES (AND RELATED BACTERIA) TRANSMITTED THROUGH FOODS

50.6.1 Coryneform Bacteria

The coryneform bacteria are included in the actinomycete branch of gram-positive bacteria because of the high G+C content of their DNA. They comprise a group of aerobically growing, nonsporeforming, irregularly shaped, Gram-positive bacteria. There are many medically relevant organisms, including the primary human pathogen, *Corynebacterium diphtheriae.*[84] In addition to the well-defined diphtheria organisms, many nondiphtheria corynebacteria exist, some of which have a pathogenic role. The coryneform bacteria have been associated with an increasing number of cases of disease. They are among the most ubiquitous organisms in the environment, being widely distributed in fresh and salt water, soil, and air. Nondiphtheria corynebacteria constitute a major component of the bacterial flora of human skin. The *C. diphtheriae* group includes the four biotypes of *C. diphtheriae* as well as *C. pseudotuberculosis* and *C. ulcerans.*[84] Not all *C. diphtheriae* are toxinogenic, but all of these species can harbor the phage-mediated diphtheria toxin gene, βtox. The classic symptom of diphtheria is a pharyngeal lesion consisting of a tightly adhering pseudomembrane. The exotoxin is produced by the organism in the local lesion, and it is distributed throughout the body in the blood. The toxin affects the heart and peripheral nerves.

The primary source of *C. diphtheriae* is the nasopharynx of a clinical case, convalescent carriers, or foods. Human skin is the main reservoir of *C. diphtheriae* and transmission from the skin is more effective than from the throat.[84] In both tropical and temperate climates, cutaneous diphtheria is a potential source of *C. diphtheriae* infection.[44] It has been implicated in bovine mastitis and it has been isolated from udder and teat lesions. Milkborne outbreaks of diphtheria generally predate widespread immunization of children and pasteurization of milk.[24] In 1981, a possible foodborne outbreak of diphtheria occurred in the Yemen, in which one of the suspected foods was yogurt.[130] Pasteurization or boiling of milk is an essential precaution for control of corynebacteria. Toxinogenic *C. ulcerans* can cause diphtheria and it may also produce a second toxin that is unaffected by the *C. diphtheriae* antitoxin, but resembles the toxin of *C. pseudotuberculosis.*[44] *C. ulcerans* can cause mastitis in cows and has been isolated from raw milk.[109,235] In the case of an office worker who developed a sore throat caused by a toxinogenic strain of *C. ulcerans*, the source of the organism was traced to raw milk, a farm worker who was an asymptomatic carrier of *C. ulcerans*, and the organism was isolated from two cows.[20] This provides further evidence that *C. ulcerans* is a zoonosis, and adds to the justification for pasteurization of milk for improved public health.

In 1982, Lipsky et al.[153] reviewed infections caused by nondiphtheria corynebacteria. Several species are involved in human infections either as zoonoses from occupational exposure to infected animals, for example, *Corynebacterium equi* and *C. pseudotuberculosis (C. ovis)*, or as opportunistic pathogens, for example, *Corynebacterium bovis*, *Corynebacterium haemolyticum*, and *Corynebacterium xerosis. C. bovis* is a common commensal of the bovine udder that can cause mastitis, but there is no indication that human infections occur through consumption of contaminated milk.[153] Several organisms, previously considered to be pathogenic corynebacteria, have been transferred to other genera, for example, *Corynebacterium pyogenes* has been transferred to *Actinomyces*, and *C. haemolyticum* is reclassified as *Arcanobacterium haemolyticum.*[44] Both of these organisms are opportunistic human pathogens, but they have not been associated with foodborne disease. *Corynebacterium pseudodiphtheriticum (C. hofmannii)* occurs as a commensal of the nasopharynx of humans, but the organism does not produce toxins. It is an opportunistic pathogen causing endocarditis and urinary tract infections.[44] Nontoxinogenic strains are commonly found as part of the normal flora of the upper respiratory tract.[183] There are other coryneform bacteria belonging to the genera *Brevibacterium* and *Propionibacterium* that have been implicated as opportunistic pathogens; but those species associated with foods, *B. linens* in surface-ripened, smear-type cheeses, and *P. shermanii* in Swiss-style cheeses have not been cited among opportunistic pathogens of these genera.[84]

50.6.2 *Mycobacteriaceae*

The mycobacteria are a large heterogeneous group of acid- and alcohol-fast, nonsporeforming bacilli that are found in soil, water, food, and animals. The pathogenic "tubercle bacilli" are the best known and

Mycobacterium tuberculosis, the cause of traditional human tuberculosis, was chosen as the type species for the genus. Nontuberculous mycobacteria (NTM) or mycobacteria other than tuberculosis (MOTT) became known as "atypical mycobacteria" but they are in fact "typical" mycobacteria.[125] The pathogenic mycobacteria include *M. tuberculosis*, *Mycobacterium bovis*, *Mycobacterium africanum*, and *Mycobacterium microti*.[95] *M. bovis* was the primary organism of foodborne tuberculosis.[36] Cow's milk was incriminated as a source of tuberculosis in 1846. Three types of "tubercle bacilli" (human, bovine, and avian), as well as many saprophytic mycobacteria, have been identified. Bovine strains caused pulmonary and extrapulmonary tuberculosis in humans;[36] whereas, the avian strain *Mycobacterium avium* was considered to cause tuberculosis of poultry and swine but not humans. The incidence of bovine tuberculosis decreased dramatically in developed countries because of active control programs for dairy herds and other livestock; however, the host range on *M. bovis* is great and includes animal species from badgers to seals.[95] Despite the marked decrease in tuberculosis in developed countries, it remains a major concern in world health.[48] The HIV pandemic has drawn attention to this, but most cases of tuberculosis are not HIV-related.[48,95] It is generally considered that only a few organisms are necessary to cause a respiratory infection; however, except in children, several million organisms appear to be necessary to cause infection by the intestinal route.[82]

Since the 1950s, there has been an increasing reported frequency of NTM disease. This has been attributed to both an increased number of immunocompromised patients and improved technical capabilities of clinical laboratories. The *Mycobacterium avium* complex (MAC) consists of *M. avium* and *Mycobacterium intracellulare*. Originally MAC included *Mycobacterium scrofulaceum*, but this is now considered to be a distinct species.[73] *M. avium* causes human disease, especially in AIDS patients. The *M. avium-M. intracellulare* organisms cause human disease worldwide, especially in northern temperate countries such as Canada, Europe, Japan, and the United States (US).[125] MAC are ubiquitous, and they have been isolated from fresh and salt water, soil, plants, bedding material, and house dust.[125] *M. avium* is responsible for most of the tuberculous lesions found in poultry and swine.[125] Pork and poultry meat could be a source of these organisms, especially if they are not sufficiently cooked. *M. avium* commonly is excreted in feces of birds but not swine, and the organisms can persist in the soil for long periods of time. Direct transmission of *M. avium* from animals to humans is considered to be rare. The primary route of infection in AIDS patients is by colonization of the gastrointestinal tract with large numbers of mycobacteria that infiltrate the intestinal mucosa and subsequently cause bacteremia.[46] Gastric achlorhydria and oral antibiotics are suspected in *M. avium* infections.[125] The thermal death time of *M. bovis* in milk is such that standard pasteurization treatments are expected to destroy the organism with a considerable margin of safety.[135] At 60° C, *M. bovis* dies rapidly in meats.[166] *M. avium-M. intracellulare* organisms are more heat-resistant than *M. bovis*, and they require heating to 71.1° C for 2 minutes to achieve a 12D kill in meat.[166,167]

M. scrofulaceum has been associated with infected lymph nodes in children. It has been isolated from raw milk and other dairy products,[31,162] raw oysters,[120] and water.[73] *Mycobacterium fortuitum* is one of a group of rapidly growing mycobacteria that cause opportunistic focal and disseminated human infections and have been isolated from water, soil, and raw milk.[62] *Mycobacterium gordonae*, previously known as "tap water bacillus" or *Mycobacterium aquae*, has been recovered also from raw milk[120] and can multiply in soil.[218] *M. gordonae* is considered to be nonpathogenic, except under unusual circumstances.[236] Prior to the AIDS epidemic, NTM infections due to *Mycobacterium kansasii* were relatively important, but its importance has been eclipsed by MAC infections. Its reservoir is unknown, but it is occasionally cultured from nonhuman sources, such as water.[236] A major change in awareness of human mycobacterial diseases has come about with the HIV pandemic.

Person-to-person transmission of NTM is rare; therefore, infections are probably derived from the natural environment, where the organisms abound. Organisms of the MAC complex have occasionally been associated with diseases of animals, and they have been isolated from raw milk, cheese, ice cream, and butter,[31] but the principal source of NTM seems to be water.[73] There are many questions to be answered about the changing epidemiology of NTM in both immunocompetent and immunosuppressed individuals. In immunosuppressed patients it appears that colonization of the intestine is a major step in the pathogenesis of the disease, making water and food the most likely sources of infection. The mycobacteria generally are hardy organisms that survive for long periods of time in the environment and they can be difficult to eliminate with disinfecting chemicals.

A role for mycobacteria in the etiology of Crohn's disease—an inflammatory bowel disease analogous to infectious ileitis in ruminants, known as Johne's disease—has long been the subject of speculation. Johne's and Crohn's diseases have been associated with *M. paratuberculosis* and *M. avium* A/I (the predominant strain causing tuberculosis of animals and birds).[165] *M. paratuberculosis* is always assumed to be pathogenic.[165] Crohn's disease is most likely a multifactorial disease involving genetic, environmental, and infectious elements. The association of these organisms with animal tuberculosis compels the question of food as a source of infections in humans, if the same organisms can be confirmed as causative agents in Crohn's disease. For further information, see reviews by Chiodini[32] and McFadden and Fidler.[165]

50.7 ZOONOSES TRANSMITTED THROUGH FOODS

Zoonoses are infectious diseases that can be contracted by humans in which the pathogen is normally associated with an animal population. They are rare in developed countries, but they still ravage the populations of developing countries. More than 150 zoonoses have been described, some of which can be foodborne, such as anthrax, bovine tuberculosis, brucellosis, Q fever, and some *Salmonella* infections. Zoonoses are not limited to bacteria; many parasites and some viruses are also involved.

50.7.1 Anthrax

Herbivores are highly susceptible to anthrax, whereas swine and humans are relatively resistant.[206] Immunization has decreased its incidence among farm animals, but the disease remains prevalent in many countries, and cases of human anthrax are still reported.[206] The outbreak of anthrax in Zimbabwe between 1978 and 1980 emphasized the need for ongoing animal health programs.[50] Human anthrax is classified as industrial or nonindustrial. Industrial anthrax is an occupational hazard of working in industries that process animal products, and can occur by inhalation (wool-sorters' disease). The most common method of spread of this disease is through diseased animals and carrion contaminating the soil. Human anthrax most commonly is contracted cutaneously through cuts and abrasions and rarely by ingestion.[224] Incidents of intestinal anthrax almost invariably have involved the ingestion of raw or poorly cooked meat from infected animals. Because of the severity of the disease in animals, antemortem and postmortem inspection should eliminate infected animals from the food supply. The obvious precaution of rejecting diseased and dead animals for human consumption aids in the control of intestinal anthrax. Adequate cooking of meats protects consumers from exposure to vegetative cells of *B. anthracis.* Intestinal anthrax from consumption of milk is rare because the animals are usually very sick and their milk visibly is abnormal.[24] Cutaneous infections form a characteristic pimple-like projection that forms a black eschar (similar to a scab). Intestinal anthrax develops in the same manner as cutaneous anthrax, by forming a necrotic lesion. The incubation period is usually 2 to 5 days, at which time a high temperature, general weakness, gastroenteritis (nausea, vomiting, and diarrhea), abdominal pain, and prostration may occur. The disease may progress to a generalized toxemia associated with 25% to 50% mortality.[224] Lack of motility is a major criterion for differentiating *B. anthracis* from all other *Bacillus* spp. Virulent *B. anthracis* grown at elevated CO_2 concentrations form mucoid colonies due to cell encapsulation.[60] *B. anthracis* produces a "medusa head" appearance on aging colonies on laboratory media, which often is cited as a differentiating characteristic. However, other *Bacillus* also produce this feature, including *B. cereus*, *B. thuringiensis*, and *B. cereus* var. *mycoides.*[184]

50.7.2 Brucellosis

Despite advances in the control of animal brucellosis, it remains a worldwide health concern for animals and humans. Most cases of human brucellosis can be traced to contact with animals and meat handling at abattoirs,[26–28] but a significant number of cases are contracted through unpasteurized milk and milk products. This is ongoing in Mediterranean and Middle Eastern countries, Pakistan, and Tanzania,[41] and in California an increasing incidence of foodborne transmission has been reported among people of Hispanic origin.[33] Cases of brucellosis frequently are unrecognized, and mild cases generally are underreported. The brucellae are classic organisms in bacteriology. They were recognized before the twentieth century for their causal role in Malta (undulant) fever, an incapacitating disease of humans and, separately, as the causal agent of the economically devastating Bang's disease (contagious abortion) of cattle. There are three "classic" species in the genus *Brucella*: *B. melitensis*, *B. suis*, and *B. abortus*. *B. melitensis* is a primary pathogen for goats and sheep, *B. suis* for swine, and *B. abortus* for cattle, but host specificity has declined.[173] Brucellae cause diseases of many other domesticated and semidomesticated animals, and all three species cause undulant fever in humans.[173] *B. melitensis* is the most pathogenic for humans, followed by *B. suis* and *B. abortus*. Hence, goat-raising areas such as the Mediterranean littoral and Mexico are more likely to be areas of high incidence of brucellosis due to *B. melitensis* than the US, Canada, or central Europe. In the latter areas, *B. suis* or *B. abortus* predominate.[191] The other three species, *Brucella neotomae*, *Brucella canis*, and *Brucella ovis* are referred to as the "new" species.[173] *B. canis* is a primary pathogen of dogs. It has been associated with "milder forms" of human brucellosis.[219] Brucellae isolated from sea mammals have been tentatively named *Brucella maris*.[194]

Brucellae generally grow only in the host; however, they survive well outside of the host.[173] In vivo these organisms produce L-forms, which makes them nonculturable; this is a factor contributing to their chronicity and diversity.[111] They are nonmotile, nonsporulating coccobacilli or short rods. The organisms are strict aerobes, but some grow best in an atmosphere with 5% to 10% CO_2.[173] Brucellae have fastidious growth requirements, including biotin, thiamine, nicotinamide, and traces of magnesium. They can be difficult to propagate on ordinary culture media,[42,111] some require the addition of serum, and growth is usually better in liquid rather than on solid media.[173]

Human brucellosis is primarily an occupational disease of veterinarians and meat workers.[26–28] Brucellae can be spread by aerosols and dust.[133] Foodborne cases of undulant fever occur often as a result of ingesting unpasteurized milk and milk products.[185,186] Undulant fever is a severe disease but it does not have specific signs or symptoms. Even the symptom for which it is named, a rising and falling fever, may not occur. The severity of the disease depends to some extent on the species of *Brucella* involved. The incubation period is usually 3 to 21 days, but it can be as long as 7 months. Onset of symptoms can be gradual or abrupt. In its acute form, the predominant symptoms are pyrexia, profuse sweats, chills, weakness, malaise, body aches, chest and joint pains, weight loss, and anorexia.[26,234] In its chronic form (a state of infection that has lasted more than 1 year, but bacteria usually cannot be isolated), there is a long history of bouts of fever, malaise, headache, sweating, recurrent depression, inertia, vague pains, sexual impotence, and insomnia.[234] The disease can be incapacitating, leading to permanent invalidism.[173] Complications occur in 10% to 15% of patients; osteomyelitis is the most common complication of *B. melitensis* infections. Other complications include skeletal, genitourinary, cardiovascular, and neurological conditions.

In animals, the organisms localize in the uterus of pregnant animals and in the mammary glands of lactating females.[173] After the abortive stage, infected animals can shed brucellae intermittently in varying numbers in their milk for years.[173] Consumption of unpasteurized goat's milk cheese has been implicated in many incidents of undulant fever,[8,68,242] as has unpasteurized sheep's milk cheese.[86] Brucellae remain viable in goat's milk cheese for up to 100 days. They survive up to 6 months but not as long as 1 year in Cheddar cheese stored at 4.4° C.[91] They also survive for long periods in raw meats, but not in smoked (heated) products.[123] Meats are rarely implicated in outbreaks of undulant fever, because cooking usually is sufficient to destroy the *Brucella* organisms. Bacteriological confirmation of infection occurs in less than 20% of patients with high antibody titres. Isolation of brucellae from clinical specimens is irrefutable evidence of infection; however, diagnosis usually is based on serological results.[173] Serological detection in chronic infections can be a problem because levels of antibody titer vary with stages of the disease.[163] Instances of elevated antibody titers without infection have been recorded with animal workers. The organisms are highly invasive; however, they do not usually cause a bacteremia because they are facultative intracellular parasites.[173] This makes the disease difficult to treat with antibiotics, so prolonged antibiotic treatment is advised.[173]

Some countries have managed to eradicate brucellosis, but this is the exception rather than the rule.[185] In the US and Canada, programs designed to decrease the incidence of brucellosis have had a marked effect. In contrast, Mexico still has a high incidence of the disease. Although brucellae are resistant to environmental stress, they are killed rapidly by high temperatures, such as those used in pasteurization and for cooking (smoking) processed meats.[123] Both low-temperature holding and high-temperature, short-time methods of pasteurization of milk are able to eliminate heavy contamination with *B. abor-*

tus.[49] In the case of raw milk cheese, it appears that aging for 90 days is not sufficient to eliminate brucellae. Goat's milk is often recommended as an alternative for infants who are allergic to cow's milk. While goat's milk can be produced even more hygienically than cow's milk, the systems for handling and marketing goat's milk are not as well established and high bacterial counts have been recorded.[169,193] As with cow's milk, it would be prudent to pasteurize goat's milk before consumption. Travelers to areas where brucellosis is endemic, especially goat-raising areas, should be cautious about consuming cheeses and other dairy products prepared from unpasteurized milk.

50.7.3 Q Fever

Q (Query) fever in humans is caused by *Coxiella burnetii*, a minute, filterable, pleomorphic cell that is generally Gram-negative.[93] *C. burnetii* originally was named *Rickettsia burneti* because it is a rickettsia-like organism. It is an obligate intracellular parasite that localizes and proliferates in cell vacuoles, as opposed to *Rickettsia* species, which grow within the cell cytoplasm. *C. burnetii* is also differentiated from typical rickettsiae by its G+C content of 42% compared with 29% to 33% for other rickettsiae.[190] It is remarkably resistant to physical and chemical stress. The organism generally is regarded as a nonspore former; however, spore-like formations were observed in the periplasmic space of large cell variants.[164] "Spore" formation could account for the exceptional resistance of *C. burnetii* to adverse conditions.

Q fever was first described among meat plant workers in Brisbane, Australia, in 1935.[53] Since then, it has become recognized worldwide as a disease of humans. Q fever is enzootic but generally asymptomatic in cattle, sheep, goats, and other animals. The illness is usually contracted by humans as an occupational disease. Typical features of Q fever in humans include an initial fever, followed by malaise, anorexia, muscular pain, and intense headache. Misdiagnosis is possible because the symptoms resemble viral influenza. During the febrile stage, bacteremia occurs and the organism can be recovered from urine. A gradual abatement of fever occurs after 1 to 2 weeks, and the organism disappears from the blood. The usual incubation period is 2 to 4 weeks, varying with the route of exposure, the infective dose, and the age of the individual.[54] Complicating sequelae include coughing, chest pain, liver damage, and endocarditis in latent or chronic cases.[190] The incidence of Q fever is probably much greater than reported.

The most common route of transmission from animals to humans is by aerosols, especially from parturient dairy cows, sheep, goats, and other animals, including cats and dogs. The principal modes of infection include inhalation of contaminated dust at meat plants and dairies, handling and ingestion of contaminated meat or milk, and handling of infected carcasses.[12] Most evidence of transmission of *C. burnetii* by milk is circumstantial. A common source outbreak from raw milk has been reported;[23] however, in a study in which contaminated raw milk was ingested by human volunteers, infection did not occur.[148] In milk, *C. burnetii* is more resistant to heat treatment than *M. tuberculosis*. Heating milk at 62.8° C for 30 minutes and 71.1° C for 15 seconds is sufficient to kill *C. burnetii*. These time-temperature standards have been adopted for pasteurization to prevent milkborne Q fever.[66]

50.7.4 Leptospirosis

This disease is thought to be the most widespread zoonosis in the world. The causative agent, *Leptospira* spp., has a natural reservoir in wild animals, particularly rodents, and domesticated animals, including cattle and dogs.[227] *Leptospira* are aerobic spirochetes that are motile, containing two periplasmic flagella inserted subterminally at opposite ends of the cell.[4] *Leptospira interrogans* is a pathogen that causes acute, febrile, systemic disease of humans and other mammals. Pathogenic and saprophytic strains are morphologically and biochemically indistinguishable. The rat *(Rattus norvegicus)* is the principal carrier of *L. interrogans* var. *icterohaemorrhagiae.*[102] Humans are an accidental host of leptospiral infections. The disease is primarily an occupational risk for veterinarians, dairy and hog farmers, and meat, poultry, and fish processors.[4,227] Leptospiraemia at the time of onset of disease persists for approximately 1 week. During the acute phase, leptospires can be detected in body fluids, including milk. Thereafter, the organisms become localized in the kidney tubules, whence they contaminate the urine of infected animals.[4] Cattle-associated leptospirosis caused by serovar *hardjo* of *L. interrogans* var. *hebdomadis*[17,227] causes a milder form of leptospirosis in humans that is a flu-like illness with symptoms including fever and headache, in which mental confusion often occurs. Milk from cows with acute leptospirosis could be contaminated with *Leptospira* spp. The incidence of foodborne leptospirosis is limited because of a leptosporicidal effect in raw milk that causes viable cells to disappear within 3 hours.[139]

50.7.5 Erysipelas

Erysipelothrix rhusiopathiae, also known as *Erysipelothrix insidiosa,* is a microaerophilic, nonmotile, Gram-positive rod belonging to the family *Corynebacteriaceae.*[230] The Gram-stain decolorizes rapidly, so it may appear to be Gram-negative.[98] *E. rhusiopathiae* is widely distributed in nature, usually associated with decaying organic matter. It is generally ubiquitous to the environment of swine.[238,239] *E. rhusiopathiae* is pathogenic for swine,[238] but humans are relatively immune to infection, except as an occupational disease through contact with infected animals or by handling contaminated animal products, including pork, poultry, and fish.[98,230] The most common form of human infection is a mild, localized inflammatory, nonsuppurative lesion (erysipeloid) on the fingers or hands.[98,230] This form of the disease is self-limiting. A severe, generalized cutaneous form, and sepsis with or without cutaneous involvement can occur, with endocarditis as a possible but rare sequela.[98,230] *E. rhusiopathiae* infection caused by ingestion is rare; however, the organism survives salting, pickling, and smoking treatments,[98] and it survives in such meats for 1 to 3 months.[24] The organism commonly can be isolated from work tables and pork in meat plants.

50.7.6 Tularaemia

Francisella tularensis, the causative agent of tularaemia, is a small, aerobic, nonmotile, faintly staining Gram-negative pleomorphic coccobacillus or rod, which may possess a single flagellum.[231] There are many ways in which this organism is transmitted to humans. The principal mode of transmission is from blood-sucking arthropods, especially ticks, which serve not only as the main vector but also as the main reservoir of the organism.[199] Ingestion of insufficiently cooked, infected wild rabbit meat, contaminated water, or rodent-contaminated foods has been implicated in infection.[118] The clinical symptoms associated with the disease depend on the mode of transmission. The typhoidal form is associated with ingestion of contaminated meat or water. The symptoms resemble typhoid, including fever, prostration, nausea, vomiting, abdominal pain, and diarrhea. Ulcerative lesions of the buccal mucosa, pharynx, and intestine can occur, and the cervical, pharyngeal, and mesenteric lymph nodes can become involved.[69] The organism is extremely virulent. As few as 10 to 50 organisms cause infection subcutaneously or by the respiratory route; however, doses as high as 10^{10} organisms are considered necessary for infection by the gastrointestinal route.[24,69] The disease is limited to the northern hemisphere, where it has been associated with approximately 100 species of wild mammals, 9 species of domesticated animals, 25 species of birds, and several species of fish.[118] Despite this, animals are not considered to be a real reservoir of these organisms. Domesticated rabbits are susceptible to tularaemia, but they are rarely infected.[24] *F. tularensis* retains its virulence for long periods during frozen storage in rabbit meat, but the organism is not heat-resistant and can be killed by exposure to 56° C to 58° C,[24] making its survival in appropriately cooked meat unlikely.

50.7.7 Intestinal Spirochetosis

Spirochetes have long been known to be present in the human intestinal tract, but their clinical significance is uncertain. Some investigators have reported that massive infestation of spirochetes in the colonic epithelium may cause diarrhea.[58,85,108] In general, very little is known about intestinal spirochetes, except for *Treponema hyodysenteriae,* which was recognized as a cause of swine dysentery in the early 1970s.[107,220] Swine dysentery is a mucohemorrhagic diarrhea, resulting from inflammation of the colon, with excess mucus production and superficial necrosis that causes hemorrhage, dehydration, and possible death.[138,220] *T. hyodysenteriae* is a large spirochete.[108] It is an anaerobic, Gram-negative, oxygen-tolerant, helical coiled organism, containing one or more periplasmic flagella at each end of the cell.[207] Treponemes are not considered to be normally part of the human intestinal microflora;[207] however, Harris et al.[108] have reported that treponemes are present in the intestinal flora of most animals, including humans. A new spirochete, *Brachyspira aalborgi,* was described as a parasite of humans.[121] The treponemes are host-associated organisms, and *T. hyodysenteriae* causing swine dysentery might not be pathogenic for humans. Anaerobic spirochetes are difficult to grow in the laboratory; however, media containing 4 mg spectinomycin ml^{-1} will allow selective growth of *T. hyodysenteriae.*[209] At this time, *T. hyodysenteriae* is not implicated as a human pathogen, but it will be interesting to observe the future developments in our knowledge of this organism and other intestinal spirochetes.

50.8 CONCLUDING REMARKS

The challenge of writing a review on the less recognized and suspected foodborne bacterial pathogens has changed dramatically with the acceptance by clinical microbiologists that production of disease does not reside solely with the pathogenic and virulence properties of the microorganisms but also with the health status of the host.[126] This brings into question the safety of refrigerated and fermented foods, as well as many raw vegetables, in which large populations of viable bacteria could be present at the time of consumption. It is clear that the general spoilage and fermentation bacteria do not have established virulence characteristics, but that they can be opportunistic pathogens. The best illustration of this is the fact that all of the lactic acid bacteria involved in lactic fermentation of foods and bifidobacteria that are used as probiotic cultures have been implicated in cases of human infection; however, individuals who become infected with these bacteria almost invariably have an underlying disease and, in the case of leuconostoc and pediococcus infections, they have usually been treated with vancomycin for another infection. Both leuconostoc and pediococci are vancomycin-resistant.[71] Consumer demand for minimally processed foods with a long refrigerated storage life, which can be achieved with vacuum or modified atmosphere packaged foods with elevated levels of carbon dioxide, provides a niche for the growth of lactic acid bacteria. This includes fermented dairy products and fermented meats, such as chill-stored vacuum-packaged, sliced processed meats. It is prudent for immunocompromised individuals to avoid such foods in their diet unless they are heated to internal temperature of 70° C before consumption. Despite this, it is reasonable to conclude that these foods represent an extremely low level of risk for the population at large. Unfortunately, for susceptible individuals, even the irradiation of foods would not solve the problem because the most likely surviving organisms are lactic acid bacteria.[110]

In contrast, the enterococci represent a much more serious dilemma for food safety. It was suggested by Bryan[24] that specific strains of enterococci may have virulence traits. This has not been demonstrated to date, but it is clear that the enterococci are more likely to become established as potential pathogens than the closely related lactic acid bacteria. The enterococci are commonly associated with foods as fecal contaminants, but their resistance to the extraenteral environment, heat, and sanitizing chemicals makes them a natural microorganism to survive in a food processing environment. *E. faecalis* is the principal species involved in human infections, but infections due to vancomycin-resistant strains (VRE) of *E. faecium* are causing concern.[97] The safety of enterococci is a challenge for food technology and public health. While enterococci are recognized as a major concern in nosocomial infections, especially with VRE, the enterococci are considered as an important component of some food fermentations and they are used by some people as probiotics. Clearly, clarification of these anomalies is required.

The Enterobacteriaceae represent an interesting source of potential or opportunistic pathogens in the food supply. Enterotoxigenic strains of both *C. freundii* and *K. pneumoniae* can be considered foodborne pathogens in the same way that specific strains of *E. coli* have become recognized foodborne pathogens. Until the outbreak of hemorrhagic colitis and HUS from *C. freundii* in parsley butter in 1995,[223] it was assumed that the most likely type of enteropathogenicity in other Enterobacteriaceae would be cholera-like enterotoxigenicity, not the shiga-like enterocolitis. The possibility that these strains also have a low infective dose represents an added challenge for food safety. In general, the Enterobacteriaceae do not grow at refrigeration temperatures, but even in the case of *Yersinia enterocolitic*, which is psychrotrophic, refrigerated foods have not been implicated in foodborne illness. Other species of Enterobacteriaceae are psychrotrophic, including *Pantoea agglomerans* and *Serratia liquefaciens*, but their role in food spoilage or as potential enteropathogens is not known. Strains of other Enterobacteriaceae, such as *H. alvei*, seem more likely to become a concern in food safety than the psychrotrophic species.

Ensuring the microbial safety of foods in the future will present many challenges for food technologists and public health authorities.

51.1 INTRODUCTION

Protozoa are micro-organisms with either simple or complex structures contained within a single cell, and equally simple or intricate life cycles that vary considerably depending on the species. Since their discovery, some 65,000 species have been described.[153] Protozoan parasites are responsible for some of the most globally important diseases of man and animals throughout the world. Malaria, for example, affects 280 million people annually, of which 110 million develop clinical disease each year.[143] Protozoan parasites often have complex life cycles with transmission occurring between two or more species of host either via biting or blood-feeding arthropod vectors, or by predation involving ingestion of tissue stages present in infected meat. Many of the protozoa with a more simple and direct life cycle can encyst, ensuring survival and a means of transmission from one host to another.

Outbreaks of gastrointestinal disease in man associated with foodborne and waterborne microorganisms have received much publicity against a background of an ever-expanding range and prevalence of diseases. In the United Kingdom (UK), there were 4,317 and 5,294 reports of gastrointestinal disease caused by *Cryptosporidium* and *Giardia*, respectively, reported throughout England and Wales in 1997.[54] In many cases, infections due to protozoan parasites are the result of poor hygiene and occur most often among travelers, particularly those visiting underdeveloped countries. However, an increasing number of opportunistic protozoan infections are reported in the elderly or the immunocompromised resident in industrialized countries.

Reports of foodborne transmission of protozoa have been relatively uncommon; however, foodborne disease due to protozoa may be more common than reports suggest, possibly underdetected by a factor of 10 or more.[44] In many foodborne outbreaks, an etiological agent is identified in less than half of cases.[16,52] In contrast, protozoa often are implicated in waterborne gastrointestinal disease with several large-scale disease outbreaks reported throughout the world. It is probably true to say, though, that prevention and control of protozoal disease outbreaks have been hindered by a lack of surveillance procedures and limited availability of appropriate diagnostic tests for protozoan parasites, particularly in food.

Some protozoan parasites involved in foodborne and waterborne disease outbreaks also occur in animals. With some of these infections there is good evidence for zoonotic transmission; however, in many cases conclusive evidence for animal-to-man transmission is lacking.

Of nearly 40 species of protozoa that infect humans, this chapter will describe the life cycles, incidence, symptoms, and methods of detection of some of the more well-recognized, as well as the emerging genera of foodborne and waterborne pathogens. Classification and characteristics of these protozoan parasites are summarized in Table 51–1.

A number of other protozoa have the potential for transmission by food or water. These include the following:

- *Naegleria fowleri* is a free-living, soil-dwelling amoeba that can infect the olfactory and nasal passages and is a rare cause of meningioencephalitis. The organism is transmitted via water following swimming or bathing.[163]
- *Acanthamoeba* are opportunistic pathogens that can produce encephalitis, keratitis, and pneumonitis. Infection is thought to occur via inhalation, but keratitis may be associated with transmission to the eye from domestic tap water, particularly in contact lens wearers.[229]
- *Isospora belli*, a coccidian parasite of man.
- The flagellates—*Chilomastix mesneli*, *Enteromonas hominis*, *Retortamonas intestinalis*, *Trichomonas hominis*, and *Trichomonas tenax*.
- The amoebae—*Dientamoeba fragilis*, *Entamoeba coli*, and *Iodamoeba buetschlii*.[42]

51.2 APICOMPLEXAN (COCCIDIAN) PROTOZOA

51. 2.1 *Cryptosporidium*

History. Protozoa of the coccidial genus *Cryptosporidium* are small intracellular parasites that occur throughout the animal kingdom and have been reported in many species of mammals, birds, reptiles, and fish.[89] Since the discovery of the organism,[258] the importance was overlooked for a long time, until the recognition of infection in various species of domestic animals, especially cattle and sheep, in the 1970s. The taxonomic status of *Cryptosporidium* is still not fully resolved but it is generally accepted that the species that occurs in man and other mammals is *Cryptosporidium parvum*.[57] Other species occurring in mammals are *C. muris* reported in rodents and cattle,[7,258] *C. felis* in cats,[110] and *C. wrairi* in the guinea pig.[50] These latter two species appear to be highly specific to their respective hosts.[110] In birds two species, *C. baileyi* and *C. meleagridis*, have been reported although other species may exist. *C. baileyi* is usually associated with infections of the cloacal bursa, cloaca, and respiratory tract in a number of species of birds.[155] *C. meleagridis* is thought to be the species associated with gut-related infections in turkeys.[109] The avian cryptosporidia appear to have a high host specificity for birds. However, a report of infection with *C. baileyi* in an immunosuppressed human patient[65] suggests that under certain circumstances cross-transmission to mammalian hosts may occur.

Cryptosporidium also are found in lower vertebrates. *C. sepentis* (*C. crotali*) has been reported from the stomach of snakes[27,152] and *C. nasorum* in fish.[126]

Life Cycle. The life cycle of *Cryptosporium parvum* (Figure 51–1A) is similar to that of other coccidian parasites and can be divided into excystation (release of infective sporozoites), merogony or schizogony (asexual multiplication), gametogony (sexual reproduction), and sporogony (sporozoite formation). Each intracellular stage resides within a parasitophorous vacuole confined to the microvillous region of the host cell (Figure 51–1B). The infective stage is the oocyst, which is passed into the environment by infected hosts via the feces. Unlike the situation in many species of coccidian parasite, the oocysts are fully sporulated and immediately infective when excreted, requiring no period of maturation without the host. On ingestion by a new host, sporulated oocysts excyst in the intestines, releasing free sporozoites that penetrate the microvillous border of enterocytes lining the gut epithelium. The sporozoites undergo asexual development or merogony producing mature meronts containing 6 to 8 merozoites (Figure 51–1C). These meronts rupture, releasing the merozoites that infect further host cells producing more meronts. After a period of rapid recycling, a second meront stage is produced with four merozoites, the released merozoites of which develop into microgamonts and macrogamonts. Fusion of a microgamete (male) with a macrogamete (female) produces a zygote that produces an outer wall to form the oocyst. Sporogony occurs within the host and it appears that two types of oocysts are produced; 80% develop a thick, environmentally resistant oocyst wall and are passed in the feces; 20% form thin-walled oocysts that are auto-infective and allow for further recycling.[56]

Prevalence in Man and Animals. Human infection with *C. parvum* has worldwide distribution and has become a common cause of gastrointestinal infection both in immunocompromised individuals, as an opportunistic pathogen associated with acquired immune deficiency syndrome (AIDS), and in otherwise healthy people.[261] In the relatively short time since its discovery in humans,[184] surveys have

Table 51–1 Parasitic Protozoa—Classification Based on Levine

Phylum	*Genera**	*General Characteristics*
Apicomplexa	*Cryptosporidium* *Cyclospora* *Sarcocystis* *Toxoplasma*	Apical complex (visible with electron microscope) generally consisting of polar ring, rhoptries, microneme, conoid; all species parasitic
Sarcomastigophora		
Subphylum Mastigophora	*Giardia*	One or more flagella usually present in trophozoites; asexual reproduction longitudinal
Subphylum Sarcodina	*Entamoeba*	Pseudopoda or locomotive protoplasmic flow without discrete pseudopodia; asexual reproduction by fission
(subphylum Blastocysta†)	*Blastocystis*	Pleomorphic, brightly refractile cysts with a central vacuole. Amoeboid form may occur
Ciliophora	*Balantidium*	Cilated organisms with micronucleus and macronucleus
Microspora	*Encephalitozoon* *Enterocytozoon* *Nosema* *Pleistophora* *Septata*	Unicellular spores with imperforate wall containing a uninucleate or binucleate sporoplasm and extrusion apparatus with polar tube or cap; obligatory intracellular parasite

* Genera of parasitic protozoa referred to in text only

† Jiang and He[133] suggest that *Blastocystis* should be classified in its own subphylum within the phylum sarcomastigophora

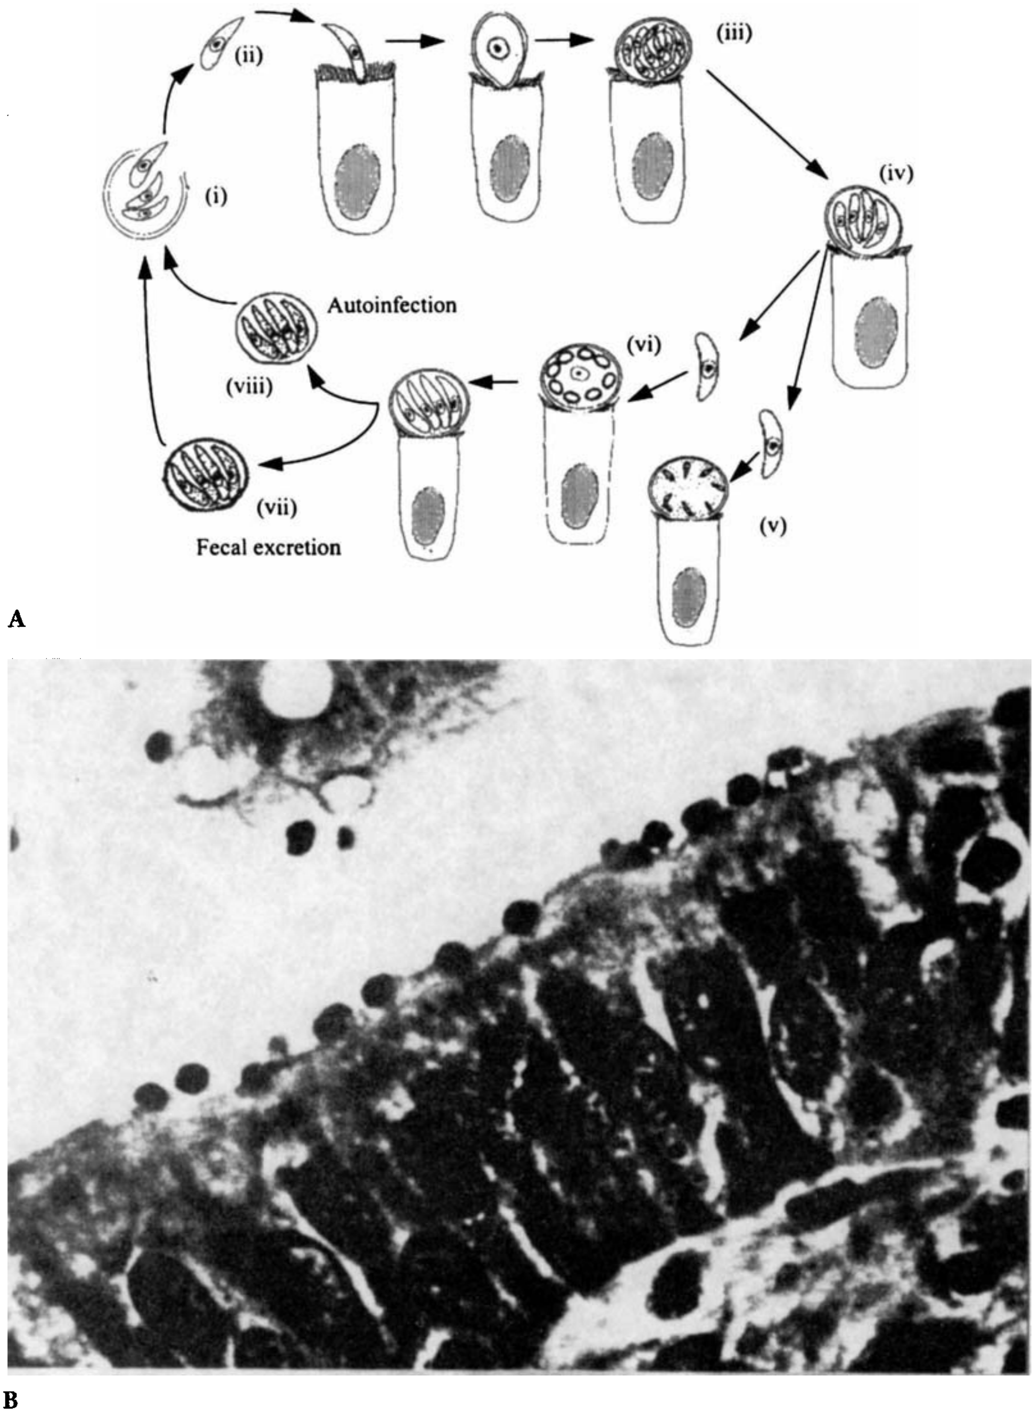
shown human infections on all six continents, in both developed and developing countries, and in urban as well as rural locations. In more industrialized countries of Europe and North America, the incidence of clinical infection is generally between 1% and 3% while elsewhere rates of between 4.9% in Asia to 10.4% in Africa have been suggested.[261] The higher prevalence in less developed countries may relate to lack of clean water, sanitation, or general crowding. Seroprevalence studies suggest a higher rate of exposure to cryptosporidiosis with levels between 25% and 35% in Europe and North America, suggesting that many *Cryptosporidium* infections are asymptomatic.[261] Cryptosporidia are found in the feces of 10% to 20% of patients with diarrhea associated with AIDS.[136,147,150,197,213,230,241,282]

Cryptosporidiosis is common in young livestock especially cattle and sheep, although pigs, goats, horses, and deer can be infected. The pathogen infects 79 species of mammals and is highly prevalent in ruminants, particularly in young calves,[89,250] and appears to be age-related. Seasonal peaks of disease have been reported to coincide with birth peaks in spring and autumn.[8] The first calves to be born often become infected without showing clinical symptoms but become sources of infection for calves that follow. Infection spreads rapidly, and later-born calves can become so heavily infected that clinical disease results. Disease associated with *C. parvum* also has been reported in neonates of sheep, goats, and deer and in nondomestic ruminants including antelope and orynx.[112] Horses, goats, and pigs can also be infected. Cryptosporidiosis has been reported in immunodeficient foals[106] as a cause of diarrhea. Most pig cryptosporidial infections are asymptomatic with the majority of infections occurring in 6- to 12-week-old pigs.[154] Clinical signs, where they do occur, include diarrhea and failure to thrive although these usually are associated with the presence of other pathogens such as *Salmonella*, *Escherichia coli*, adenovirus, or *Isospora suis*. There are only a few reports of *Cryptosporidium* infections in companion animals. Dogs, cats, and other pets occasionally are infected but they do not appear to be an important source of infection to other hosts. Given their ubiquitous occurrence, there is a large potential reservoir of infection to man and domestic animals.

Epidemiology and Transmission. Transmission from host to host is via the oocyst stage by the fecal-oral route through contaminated water, contaminated food, animal-to-person contact, or person-to-person contact. The parasite is highly infectious and seems to be one of the main causes of infectious diarrhea in many parts of the world.[261] Oocysts of *C.*



continues

Figure 51–1 Life Cycle of *Cryptosporidium parvum*. **A**, Sporulated oocysts upon ingestion, excyst (i) in the intestines releasing free sporozoites (ii), which penetrate the microvillous border of gut epithelial cells. The sporozoites undergo asexual reproduction, merogony, to form first generation meronts (iii) containing 6 to 8 merozoites. These rupture releasing merozoites, which form second generation meronts (iv) with 4 merozoites. Released merozoites produce either microgametocytes (v) or macrogametocysts (vi). Fusion produces a zygote that undergoes sporogony within the gut to form either thick-walled oocysts (vii), which pass out in the feces, or thin-walled oocysts (viii) that can autoinfect further epithelial cells within the host. *Source:* Reprinted with permission from M.A. Taylor, Waterborne Parasites: A Veterinary Perspective, *Health and Hygiene*, Vol. 14, p. 56, © 1993, Royal Institute of Public Health and Hygiene. **B**, Trophozoites of *Cryptosporidium* attached to the microvillous border of gut epithelial cells. *Source:* Copyright © 1999, Ministry of Agriculture, Fisheries and Food, U.K.

parvum, unlike many other coccidia, are fully sporulated when shed and therefore are thought to be infectious immediately.[88] They survive in wet or moist conditions outside the body for weeks or months and survive longer at cold temperatures. Many mammals have been found naturally infected with *C. parvum* and have the potential, therefore, to act as reservoir hosts.

In man, person-to-person transmission is now recognized to be common and is considered to be the main route of transmission.[205,239] Zoonotic transmission has been reported from calves and lambs, particularly following educational visits to farms.[14,240] In Australia, random amplified polymorphic DNA-polymerase chain reaction (RAPD-PCR) has demonstrated geographical differences in strain isolates from different hosts, which suggests local endemnicity and zoonotic transmission.[180] Isoenzyme analysis in the UK has shown differences between human isolates and animal isolates.[168] It is not clear at this stage whether this represents isolate variation in cross-species transmission between Australian or UK isolates or just differences in the strain typing methods. Recent evidence suggests that two distinct strains and transmission cycles of *C. parvum* exist, arbitrarily designated genotype 1 (predominantly of human origin) and genotype 2 (predominantly of animal origin).[12,196]

In many instances where *Cryptosporidium* is diagnosed in animals, it appears that infections usually originate from the same host species. In animals, the primary route of infection is likely to be the direct animal-to-animal fecal-oral route. Thus in calves, for example, overcrowding, stress of early weaning, transport, and marketing, together with low levels of hygiene increase the risk of clinical infections. In lambs, chilling due to adverse weather conditions in the neonatal period, intercurrent infections, or nutritional or mineral deficiencies could exacerbate or increase the likelihood of disease. Infection in these cases is likely to occur through grooming, nuzzling, coprophagy, fecal soiling by direct contact with infected animals, or indirectly through consumption of contaminated feed or environmental sources including pasture and water.[250] Heavy infections can lead to high levels of environmental contamination, which influences the rate of infection in susceptible hosts. Infected calves and lambs may shed 10^7 oocysts g^{-1} of feces and can excrete up to 10^{10} oocysts over 14 days.[46] *Cryptosporidium muris* has been isolated from wild mice in the UK,[48] but the role of rodents in transmission of cryptosporidiosis is still unclear.

Although foodborne transmission is a distinct possibility, there is little documentation of such transmission. As with other enteric protozoa, there is a potential for transmission by foodhandlers who are excreting oocysts. Direct incrimination of foodborne transmission of *Cryptosporidium* is hampered by the lack of culture techniques for the recovery of small numbers of oocysts. Epidemiological evidence points to the consumption of certain foods (raw sausage, offal, and milk) as a risk factor.[43,44,45,99] Tripe has been suspected as a source of infection.[182] Raw meat may be a potential source of human infection through cross-contamination at abattoirs where large numbers of oocysts have been detected in untreated effluent.[138] Acute gastroenteritis occurred in a group of people who had consumed chicken salad contaminated with *C. parvum*.[21] Consumption of raw milk has also been incriminated in outbreaks in the UK,[257,284] Poland,[141] and Russia.[218] In one outbreak in the United States (US) cryptosporidiosis was reported in children drinking school milk and linked to a defective on-farm pasteurization plant.[102] Outbreaks of cryptosporidiosis have been reported among people drinking freshly pressed, unpasteurized cider.[174,177] Fallen apples contaminated with animal manure have been incriminated as the presumed source of infection.

Cryptosporidium oocysts are prevalent in surface waters.[119] Contamination is frequently due to human or animal feces.[217] Adverse weather conditions such as heavy rain and floods can cause sewage overflow and increase agricultural and urban runoff resulting in water contamination.[156] Accidental pollution and heavy rainfall, especially following the application of manure to agricultural land, can rapidly increase the levels of contamination. In many instances, the species of *Cryptosporidium* is not identified, so the infectivity for humans is not determined. Concern has increased following a report that *C. parvum* could be experimentally transmitted to aquatic lower vertebrates (fish, amphibians, and reptiles) and then back to mammals.[9] Waterfowl also have been shown to excrete *C. parvum* oocysts, acting as mechanical vectors and disseminating the pathogen in the environment.[110]

Outbreaks of cryptosporidiosis associated with contaminated drinking water have been reported from a number of countries including large outbreaks in the US and UK. The largest outbreak of waterborne cryptosporidiosis was reported in Milwaukee, Wisconsin, with an estimated 403,000 people becoming ill.[169] In the UK, outbreaks of cryptosporidiosis have been reported from a number of counties associated with contaminated drinking water[100,139,214] or contaminated swimming pools.[98]

Clinical Signs. *Cryptosporidium* infection was first associated with severe diarrhea in humans but other clinical profiles are recognized.[261] The diarrhea is more profuse in immunocompromised people than in immunocompetent persons. In such severely immunocompromised persons as those with AIDS, infections are of long duration, often followed by death. Other clinical signs can include abdominal pain, nausea, vomiting, and fever. The onset of cryptosporidiosis often begins with an influenza-like illness. Nonspecific symptoms include loss of appetite, malaise, muscle pain, weakness, and headache. The infective dose can be small, approximately 1,000 oocysts or less, and the time from exposure until clinical illness can range from 5 to 21 days.

In animals, particularly young ruminants, symptoms include profuse watery diarrhea, abdominal pain, and dehydration, which may be followed by recovery and immunity to further clinical episodes. Disease is often associated with the presence of other organisms, notably enterotoxogenic *Escherichia coli*, *Salmonella*, *Clostridium perfringens*, rotavirus, and coronavirus,[57] all of which may contribute to the neonatal diarrhea complex, although evidence suggests that *C. parvum* is a primary pathogen in its own right.[8]

Methods of Detection. The epidemiological investigation of foodborne cryptosporidiosis and the detection of *Cryptosporidium* in food have been limited by the lack of efficient detection methods. At present, there are no convenient, specific tests for *Cryptosporidium* in food. Methods adapted for clinical diagnosis or used by the water industry offer the only means of detection. A variety of techniques have been developed for processing fecal specimens to obtain and identify oocysts.[58] The oocyst of *Cryptosporidium parvum* is approximately 4 μm to 6 μm in diameter. Current laboratory methods of diagnosis of clinical cryptosporidiosis rely on the direct examination of fecal smears or fecal concentration and subsequent microscopic examination. In food, and in treated or environmental samples, oocysts usually are present in low numbers, requiring concentration techniques in order to increase the chances of recovery.[149]

Concentration of oocysts from water is possible by filtration of large volumes of water using cartridge or membrane filtration, or smaller volumes using a calcium carbonate flocculation technique.[96] In food, similar concentration techniques may be applied prior to detection.[149]

Several stains have been used to differentiate oocysts from surrounding debris, including acid-fast stains, Giemsa, Gram stain, methenamine silver, Periodic Acid Shift (PAS), and others. These methods, which are summarized in Table 51–2, are generally considered to be adequate for detection of *Cryptosporidium* oocysts in samples from acute infections where many oocysts are present. Acid-fast stains are fast, relatively easy to use, accurate, and inexpensive. Most oocysts stain red, differentiating them from green-stained yeasts of the same size (4.5 μm to 5 μm diameter) and shape. Fluorescent stains alone or combined with specific anti-*C. parvum* antibody have also been used successfully. The detection limits using such techniques may be as high as 500,000 oocysts g^{-1} of feces.[271]

In human diarrheal cases, a further problem faced is the microscopic misidentification of *Cryptosporidium* as *Cyclospora*.[283] These organisms stain similarly using acid-fast stains. *Cyclospora* cysts (8 μm to 10 μm, two sporocysts with 2 sporozoites [see Section 51.2.2]) are slightly larger than *C. parvum* oocysts (4 μm to 6 μm, four sporozoites without sporocysts), but very similar in size to *C. muris* (7.4 μm × 5-6 μm). The internal structures are not clearly visible without the use of electron microscopy.

Speciation of *Cryptosporidium* is difficult, if not impossible, using these conventional techniques. A range of molecular and immunological techniques has been developed. Monoclonal antibodies (mAbs) have been produced that are specific to polypeptides, with the ability to distinguish sporozoites of *C. parvum*, which is potentially the most pathogenic species to mammals, from those of other cryptosporidia. mAbs have become the basis for alternative detection methods that involve immunofluorescence (IF) or enzyme-linked immunosorbent assays (ELISA).[222] Commercially available ELISA and IF kits, based on genus-specific monoclonal antibodies to oocyst surface proteins, are available for use in diagnostic laboratories, but at present there are no mAbs that can be used to discriminate between species of intact oocysts.[253] The detection limits of ELISAs and IF tests are similar to those stated above for the examination of stained fecal smears and depend primarily on the concentration methods employed to prepare the sample.[271,273]

DNA-based techniques, using PCR, have been investigated for use in the detection of *Cryptosporidium*.[149,151,275] Before such techniques are adopted they require rigorous testing and comparison with existing methodologies. They do, however, offer the advantage of increased sensitivity, when used in conjunction with immuno-magnetic separation (IMS).[274]

Prevention and Control. To prevent or control cryptosporidiosis, oocysts must be eliminated from the environment or rendered nonviable, or susceptible people must avoid contact with known sources of oocysts such as infected animals or people and contaminated environments.[85] Because immunocompromised patients are at greater risk from cryptosporidiosis, specific measures have been recommended.[140] These include minimizing oral exposure to water from lakes, streams, and public swimming pools, and treating drinking water by either boiling or by using a filter capable of removing particles greater than 1 μm in size. The safety of bottled water varies from supplier to supplier. Heating water to temperatures above 72.4° C inactivates *C. parvum* oocysts.[84]

A number of control measures are used for the treatment of potable water to render it safe for drinking; however, unless prepared specially, no water is totally clear of particles under 10 μm and the addition of chlorine as a final disinfectant for bacteria has no effect on oocysts. Indeed, few disinfectants have been found effective within a relatively short period of exposure and the application of these chemicals is relatively impractical. A review of water purification methods for removal of oocysts is given by Badenoch.[14] The use of slow sand filtration and chemical flocculation in the water treatment process can increase the removal of oocysts.

Table 51–2 Summary of Laboratory Methods Available for Detection of *Cryptosporidium*

Technique	*Method(s)*	*Sensitivity (oocysts g^{-1})*	*Speciation*	*Use*
Smear/Stains	Ziehl Neelson (ZN)	>100,000	Based on morphology	Clinical diagnosis
	Auramine Phenol (AP)	>50,000		
Concentration	Flotation-NaCl-Sucrose Formalin-ethyl acetate	>500,000	Based on morphology	Clinical diagnosis
	Flotation + stain (eg, Sucrose + AP)	>5,000	Based on morphology	Clinical diagnosis
	Cartridge/membrane filtration	N/A	Based on morphology	Monitoring of water and environmental samples
Immunological	IFA	>50,000	Based on morphology	Clinical diagnosis
	ELISA	>50,000	Not possible	Clinical diagnosis
	Sample concentration and immunofluorescence	>5,000	Based on morphology	Clinical diagnosis
	Flow cytometry	N/A	Based on morphology	Monitoring of water and environmental samples; tracing asymptomatic carriers
Biophysical and Biochemical Techniques	Isoenzyme analysis	N/A	Based on banding patterns	Isolate characterization
	Two-dimensional electrophoresis	N/A	Based on banding patterns	Isolate characterization
DNA-Based Techniques	PCR	<100	Specific probes	Monitoring of water and environmental samples; tracing asymptomatic carriers
	RFLP analysis	N/A	Based on banding patterns	Isolate characterization
	RAPD-PCR	N/A	Based on banding patterns	Isolate characterization
	DNA sequencing	N/A	Based on analysis of sequence data	Isolate characterization

IFA–Immunofluorescence assay; ELISA–Enzyme-linked immunosorbent assay; PCR–polymerase chain reaction; RFLP-Restriction fragment length polymorphism; RAPD-PCR—Random Amplified Polymorphic DNA–Polymerase Chain Reaction
N/A—not applicable

Freezing or adequate cooking of foods will destroy oocysts and thus limit foodborne transmission. Personal hygiene and sanitation can reduce oocyst numbers. Thorough washing of hands and the removal of soil from fresh vegetables can reduce the risk of hand-to-mouth or foodborne ingestion of oocysts.

Conclusion. Outbreaks of cryptosporidiosis due to foodborne transmission have rarely been reported but the high prevalence of infection in man and animals, together with the high infectivity of *Cryptosporidium parvum* and fecal-oral route of transmission, offer the potential for foodborne infections. The immunocompromised are at greatest risk and should take steps to limit exposure. The greatest potential risk comes from ingestion of fresh, raw, or uncooked foods. Avoidance of contamination of vegetables and fruits in the field, strict hygiene measures involving handling of food, and the susceptibility of the organism to freezing and cooking offer effective means of control. In contrast, waterborne transmission appears relatively common and can result in large-scale outbreaks of disease. Improvement in water catchment may reduce the potential health risks associated with the presence of oocysts in water supplies, but probably would not eliminate the problem. No single conventional treatment process is considered able to remove oocysts entirely but effective flocculation and filtration may reduce their numbers to a low level of hazard.[117] The zoonotic potential of cryptosporidiosis necessitates strict personal hygiene especially when handling young farm livestock and especially where children are concerned.

51.2.2 *Cyclospora*

History. *Cyclospora* are coccidian parasites reported from a number of animals that have assumed importance more recently in man, with worldwide reports of the presence of "cyanobacterium-like bodies" in the feces of immunocompetent and immunocompromised patients with diarrhea.[190] These organisms are now recognized as *Cyclospora cayetanensis* and are a cause of protracted diarrhea in humans. Parasites of this genus were first reported in the late 19th century and since have been described in insectivorous mammals,[80,92,93] nonhuman primates,[242] and snakes.[195,200,201]

It is thought that initial cases of infection in man were either reported as unidentified coccidian parasites[11] probably misidentified as *Isospora*,[215] *Cryptosporidium*,[244] or described as cyanobacterium-like organisms.[157]

Life Cycle. The life cycle in animals typically is coccidian and is likely to be similar in humans. Infection commences with ingestion of the sporulated oocyst (containing 2 sporocysts each with 2 sporozoites). Development occurs within the gut epithelium with asexual development (merogony) producing merozoites. The number of merogony stages varies, but ultimately the last meront stage produces merozoites that develop into gametocytes to product a zygote and then oocyst. Oocysts are passed in the feces and undergo further development (sporogony) outside the body to produce the final infective, fully sporulated oocyst stage. Sporulation is prolonged, taking from 2 weeks to 4 to 6 months depending on temperature.[244]

Prevalence in Man and Animals. Although *Cyclospora* appears to be widely distributed throughout the world, the prevalence of infection in man and animals worldwide is unknown. It has been reported in North, Central, and South America, Eastern Europe, India, South Africa, and Southeast Asia.[243] In Canada and the US, approximately 1 in 1,000 human fecal samples from patients being investigated for gastrointestinal abnormalities were found to be positive[25,187] although the prevalence in the general population was considered to be generally lower. In the UK, *Cyclospora* was identified in 0.1% of 1,333 human fecal samples from healthy adults.[51] Prevalence rates of 11% have been reported among nonnative adults and children in Nepal during the rainy season.[125] In human immunodeficiency virus (HIV)-infected Haitian adults with chronic diarrhea, 11% had *Cyclospora* infection.[194]

Epidemiology and Transmission. An outbreak of *Cyclospora* occurred in a hospital in the US that pointed to water as a likely source of infection.[244] Other outbreaks of infection via drinking water have been reported,[208] and consumption of untreated water during foreign travel has been incriminated as a factor in the epidemiology of the disease.[125] More recently there have been several reports of foodborne transmission associated with the consumption of fruit in North America. A large outbreak of cyclosporiosis in the US was associated with the consumption of imported raspberries.[122] Mesclun (a mixture of various types of baby leaves of lettuce) was suspected of being the vehicle for one or possibly two outbreaks in the US in 1997.[178] The consumption of basil was suspected as a source of infection at a luncheon in Virginia.[179] Most cases of cyclosporiosis in the UK appear to be linked with foreign travel.[19]

Clinical Signs. The most typical signs of cyclosporiosis infection in man are watery diarrhea with nausea, vomiting, anorexia, bloating, abdominal cramps, fatigue, and malaise.[11,125,235,243] The incubation period ranges from 2 to 11 days.[243] Among immunocompromized hosts, *Cyclospora* infection has occurred predominantly in HIV-infected individuals. Clinical illness in these patients is prolonged and severe[125] and is associated with a high rate of recurrence.[194,236]

Methods of Detection. In fresh fecal samples, *C. cayetanensis* appears as nonrefractile cysts, 8 to 10 µm in diameter. The cyst contains a pale green morula composed of refractile, membrane-bound globules in a rosette configuration.[157] Sporulated oocysts contain two sporocysts each with two sporozoites. The internal structures are not clearly visible without the use of electron microscopy. *Cyclospora* oocysts may be confused with *Cryptosporidium* oocysts unless measurements are taken with a micrometer. The organisms stain similarly using acid fast stains. *Cyclospora* cysts are slightly larger than

C. parvum oocysts (4 μm to 6 μm); those from animals may vary in size up to 17 μm to 18 μm.[92]

Methods used for screening water samples for *Cryptosporidium* should prove equally effective for *Cyclospora* once suitable fluorescent-labeled monoclonal antibodies have been developed. Detection of *Cyclospora* on food, particularly fruit, is difficult even though methods for detecting protozoan contamination exist. Fruit juice interferes with DNA methods and fruit debris interferes with microscopy.[130]

Prevention and Control. Precautions similar to those recommended for cryptosporidiosis (see Section 51.2.1) should be taken wherever possible. In third-world countries with poor sanitation, one should only consume water that is either boiled or bottled. As most reports of cyclosporiosis occur following consumption of fresh fruit and salads, these should be washed thoroughly and food handlers should ensure good personal hygiene.

Conclusion. Based on recent reports of both waterborne and foodborne outbreaks, it is evident that *Cyclospora* is a rapidly emerging pathogen and cause of diarrheal illness in man. At this stage, little is known of potential sources and mode of contamination with the organism. The greatest potential risk appears to be from contaminated drinking water, particularly on foreign travels, and from fresh produce. As with other infections, produce to be eaten raw should be thoroughly washed, including salad vegetables and certain fruits if they have been grown in conditions exposed to fecal contamination.

51.2.3 *Sarcocystis*

History. *Sarcocystis* is one of the most prevalent parasites of livestock and infects mammals, including man, birds, and lower vertebrates.[78] About 130 different species have been reported. Controversy still exists over the generic and specific taxonomy such that the nomenclature remains confusing.[254] The parasites derive their name from the intramuscular cyst stage (sarcocyst) of the life cycle, which for many years after the discovery of these parasites was the only stage known. Cysts are found in virtually all skeletal muscles of the body including the tongue, esophagus, and diaphragm, as well as in cardiac muscle and to a lesser extent in the brain. *Sarcocystis* spp. are obligatory heteroxenous parasites, ie, both an intermediate and a definitive host need to be present for the continuation of the life cycle. Asexual reproduction (merogony) and cyst formation occur in the intermediate host, while sexual reproduction (gametogony) and oocyst maturation (sporogony) occur in the definitive host (Figure 51–2). Intermediate hosts of *Sarcocystis* are usually herbivores or omnivores that become infected by ingesting sporocysts with contaminated food or water. Definitive hosts are carnivores, which become infected by ingesting cysts contained in muscle or nervous tissue of intermediate hosts.

Most *Sarcocystis* infecting man and domestic animals are species-specific for their intermediate hosts and family-specific for their definitive hosts.[254] Intermediate as well as definitive hosts can be infected by several different *Sarcocystis.* Livestock can be intermediate hosts for several *Sarcocystis* spp. of different pathogenicity (Table 51–3). In man, two species of *Sarcocystis* have been described with varying pathogenicity. Foodborne transmission therefore occurs through the ingestion of raw or undercooked meat containing mature sarcocysts.

Life Cycle. Sarcocysts present in the muscle of the intermediate host contain large numbers of spindle-shaped bradyzoites or cystozoites (the terms being synonymous with merozoites) that appear dormant until the cyst is ingested. Following digestion by the final host, bradyzoites liberated from the cyst become active and enter cells in the intestinal lamina propria in which they develop into the sexual stages of microgametes or macrogamonts. Macrogamonts are fertilized by the sperm-like microgametes producing zygotes, which then develop into oocysts. Oocysts sporulate in the intestine, forming two sporocysts that each contain four sporozoites. Often, the thin oocyst wall ruptures during passage in the feces, with individual sporocysts shed by the infected person or animal. These sporocysts are infectious only for the same species of intermediate host that served as the original source of infection. After ingestion of sporocysts, sporozoites are liberated in the gut and find their way to arterioles throughout the body, from which they enter cells and undergo asexual multiplication, producing merozoites. These in turn leave the host cell and travel in the bloodstream to the capillaries, in which they enter new host cells and again undergo asexual multiplication to produce a second generation of merozoites. When these become mature and leave the host cell, they enter skeletal and cardiac muscle cells from which they give rise to the cyst stage (containing bradyzoites).

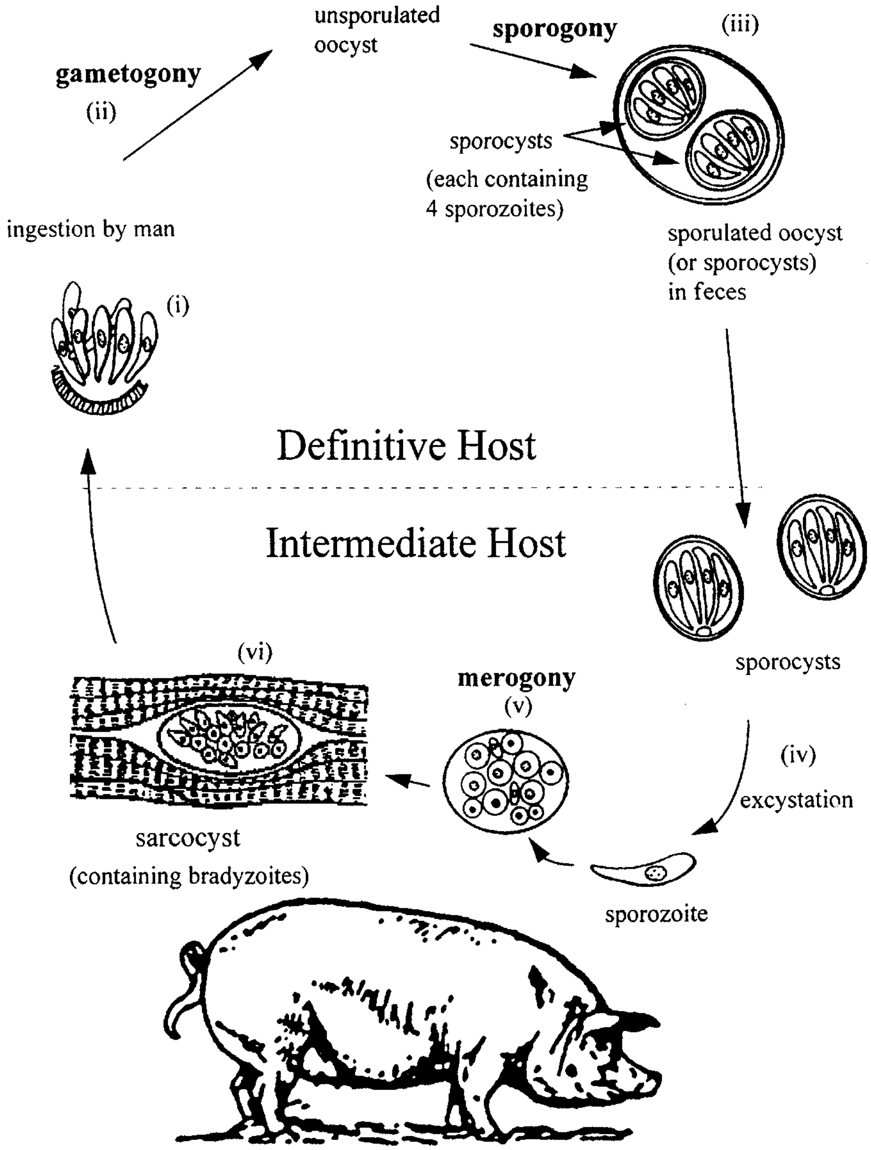

Figure 51–2 Life Cycle of *Sarcocystis suihominis*. Ingestion of sarcocysts (i), present in the muscle of the intermediate host, results in the release of bradyzoites in the small intestine of the definitive or carnivorous host. The bradyzoites penetrate the mucosa of the small intestine and develop into macro and microgametocytes [gametogony (ii)], which fuse to form zygotes released into the gut lumen as unsporulated oocysts. Oocysts sporulate in the intestine forming two sporocysts each with 4 sporozoites (iii). Rupture of the thin-walled oocysts in the intestine leads to passage of either oocysts or sporocysts (iv) into the feces. Sporozoites are released into the intestine following ingestion by the intermediate host from where they travel via the bloodstream to the blood vessels where they undergo two cycles of asexual development in the lining of endothelial cells [merogony (v)] before entering cardiac or skeletal muscle and forming sporocysts (vi) containing large numbers of bradyzoites.

Prevalence in Man and Animals. There are two known species of *Sarcocystis* that infect man: *S. hominis* (*S. bovihominis*) and *S. suihominis* (Table 51–3). There is evidence to suggest that oocysts of these species were previously referred to as *Isospora hominis*.[1] Humans also serve as the accidental intermediate host for several unidentified species of *Sarcocystis*.[17,78] Intestinal sarcocystosis in man, associated with clinical signs of gastrointestinal upset, appears to be more common in Europe than in other continents, with reports in Czechoslovakia,[105] France,[60] Germany,[91,132] and Poland.[202] Levels of in-

Table 51–3 *Sarcocystis* of Man and Domestic Animals

Intermediate Host	*Definitive Host*	*Sarcocystis*	*Pathogenicity (intermediate host)*
Cattle	Man, primates	*S. hominis (S. bovihominis)*	low
	Dog, wolf, fox	*S. cruzi (S. bovicanis)*	high
	Cat	*S. hirsuta (S. bovifelis)*	low
Sheep	Dog, fox	*S. tenella (S. ovicanis)*	high
	Dog, fox	*S. arieticanis (S. ovicanis)*	intermediate
	Cat	*S. gigantea (S. ovifelis)*	nonpathogenic
	Cat	*S. medusiformis (S. ovifelis)*	nonpathogenic
Pig	Man, primates	*S. suihominis (S. hominis)*	high
	Dog, cat	*S. miescheriana (S. suicanis)*	high
		S. porcifelis (S. suifelis)	unknown
Goat	Dog, fox	*S. capracanis*	high
	Dog	*S. hircicanis*	intermediate
	Cat	*S. moulei*	nonpathogenic
Horse	Dog	*S. bertarmi*	low
Chicken	Unknown	*S. horvathi*	unknown

fection in man may reflect cooking habits and preferences for undercooked meat.

There are three species of *Sarcocystis* affecting cattle. Only one species, *S. hominis* (*S. bovihominis*), is infective for man. Examination of various tissues suggests that most cattle worldwide are infected with *Sarcocystis*,[78] with *S. cruzi* (*S. bovicanis*), which is infective to dogs, the most prevalent. Infection of cattle with *S. hominis* appears to be fairly low in many countries, with the possible exception of Germany where up to 63% of cattle have been shown to be infected.[228] *S. hominis* can only be differentiated from *S. hirsuta* (*S. bovifelis*) by electron microscopy, and thus information on the prevalence of the former species may be misleading or inaccurate. Almost all adult sheep can be infected with *Sarcocystis* but none of these species are infective for man.[78] Of the four species, two infect dogs, *S. tenella* and *S. arieticanis* (*S. ovicanis*), and two infect cats, *S. gigantea* and *S. medusiformis* (*S. ovifelis*). The overall prevalence of *Sarcocystis* in pigs is low, between 3% and 36% worldwide.[78] Three species occur in pigs, one of which, *Sarcocystis suihominis*, is infective for man. This species has been reported in European countries with the highest prevalence in Germany.[22] The other two species found in pigs infect either dogs, *S. miescheriana* (*S. suicanis*), or cats, *S. porcifelis* (*S. suifelis*).

Epidemiology and Transmission. In most cases, humans acquire gastrointestinal sarcocystosis by ingesting raw or undercooked meat from cattle or pigs harboring mature *S. hominis* or *S. suihominis* cysts. Macroscopic cysts of *Sarcocystis* are often removed at meat inspection, although these cysts are usually of no significance to man. Some meat animals such as camels, llamas, water buffalo, and yaks harbor *Sarcocystis* in which the final host is unknown. Man may also harbor sarcocysts in striated muscle and therefore serve as the intermediate host.[17] The species and life cycle are unknown but are often collectively referred to as *S. lindemanii*. In a survey of 100 human tongue tissues taken at autopsy in Malaysia and examined histopathologically, a 21% incidence of *Sarcocystis* was found.[280] Based on the knowledge of all other *Sarcocystis* life cycles, infected human tissue would have to be eaten by a carnivore to complete the life cycle. Because there is no known predatory or scavenging cycle in nature in which human tissues are eaten regularly by carnivores, humans most likely become infected accidentally by ingestion of water contaminated by the feces of a carnivore.

Clinical Signs. Human volunteers became infected and shed oocysts in their feces following the ingestion of raw beef containing *S. hominis*,[10,220] although only one volunteer became ill. The clinical signs that appeared 3 to 6 hours after eating the beef included nausea, stomachache, and diarrhea. In contrast, volunteers who ate raw pork infected with *S. suihominis* also became infected and shed oocysts but had much more dramatic symptoms that appeared 6 to 48 hours after ingestion.[123,220] These clinical signs included bloat, nausea, loss of appetite, stomachache, vomiting, diarrhea, difficulty breathing, and rapid pulse. Volunteers who ate well-cooked meat from the same pigs developed no clinical signs.[123] *Sarcocystis* may be responsible for several idiopathic diseases in man including cardiac diseases such as cardiomyopathy and myocarditis[13,116] and rheumatic diseases.[116] It also has been suggested that *Sarcocystis* may be associated with muscle aches and fatigue as part of the chronic fatigue syndrome (CFS).[199]

In animals, most pathogenic *Sarcocystis* cause disease only in their intermediate hosts and not in their definitive hosts. Carnivores fed meat infected with a number of species of *Sarcocystis* shed sporocysts in their feces but usually appear clinically normal. Little is known about the mechanisms that cause pathogenicity and not all species are pathogenic in their intermediate hosts. Species that infect ruminants appear to be the most pathogenic with those transmitted by dogs or primates generally more pathogenic than those transmitted by cats (Table 51–3). The severity of clinical disease depends on the dose of ingested sporocysts and the immune status of the host. The uptake of a high number of sporocysts of a pathogenic *Sarcocystis*, in particular of *S. cruzi* in cattle or *S. tenella* in sheep, can lead to acute sarcocystiosis in previously uninfected animals that have not developed immunity. Of the three species infecting cattle, *S. cruzi* is the most pathogenic, causing a variety of symptoms including fever, anorexia, anemia, weight loss, weakness, muscle twitching, prostration, depressed milk yield, hypersalivation, neurological signs, and death depending on the number of sporocysts ingested.[78] In pregnant animals, acute sarcocystiosis frequently results in fetal death, abortion, or premature birth of the offspring.[87] Animals surviving a primary *Sarcocystis* infection usually acquire immunity that protects them against acute disease after challenge with the homologous species, but not after infection with a pathogenic heterologous species. Chronic sarcocystiosis of domestic livestock can result from the ingestion of a low dose of sporocysts and can cause economic losses due to reduced quality and quantity of meat. Additional economic losses occur with those species that form macroscopic cysts resulting in condemnation of whole carcasses or affected parts after slaughter.

Methods of Detection. Determination of *Sarcocystis* in meat can be made by direct observation of macroscopic cysts or microscopic examination of histological sections. Meat also can be ground and artificially digested with a mixture of pepsin and hydrochloric acid at 37° C for 1 hour, centrifuged, and the pellet examined microscopically for the presence of bradyzoites.[78]

Presumptive diagnosis of human intestinal sarcocystiosis is based on clinical signs and a medical history indicating ingestion of raw or undercooked meat. Definitive diagnosis would require identification of sporocysts in the feces. Sporocysts can be identified by concentration from fecal material, using a sucrose flotation medium and examination using bright field microscopy. Sporocysts of *S. hominis* are shed 14 to 18 days after ingesting beef and average 14.7 μm by 9.3 μm in size. Those of *S. suihominis* are shed 11 to 13 days after ingestion of pork and average 13.5 μm by 10.5 μm.

Clinical symptoms of acute sarcocystiosis in ruminants are nonspecific, and diagnosis, therefore, is currently based on the histological detection of meronts at postmortem examination. In abortions, meronts may be found in maternal tissues of the placenta, but are not found consistently in fetal membranes or tissues. In chronic sarcocystiosis, cysts can be found microscopically in skeletal or heart muscle. While cystozoites of different *Sarcocystis* are too similar morphologically to be differentiated from each other, some *Sarcocystis* can be identified in stained histological sections or squash preparations based on the morphology of their cyst wall. In many cases, a species-specific diagnosis of *Sarcocystis* cysts is not possible and requires the use of electron microscopy.

To improve the sensitivity and specificity of histological detection of *Sarcocystis* stages, several immunohistochemical methods have been developed.[118,259] However, polyclonal antisera derived from animals that have been immunized with any species of *Sarcocystis* show a high cross-reactivity with antigens of heterologous *Sarcocystis*. It is, therefore, currently not possible to differentiate between infections with pathogenic and nonpathogenic *Sarcocystis* in intermediate hosts.

Prevention and Control. Human infection with intestinal sarcocystiosis can be prevented by ensuring that meat is cooked thoroughly or frozen to kill bradyzoites in cysts. To interrupt the life cycle and prevent infection of livestock, carcasses, meat scraps, offal, or other raw or undercooked tissues should not be available to domestic or wild carnivores in areas where livestock are raised.

Conclusion. Although a widespread and common infection in domestic animals, transmission to man through ingestion of infected meat is a relatively rare occurrence. Species of *Sarcocystis* are highly host-specific, and only two species are known to infect man. The greatest potential risk therefore comes from ingestion of raw or uncooked beef or pork. Providing meat is well cooked, *Sarcocystis* should not present a serious foodborne risk. Residents or visitors to countries where raw or undercooked meat is served should beware or suffer the consequences.

51.2.4 *Toxoplasma*

History. *Toxoplasma gondii* is an obligate intracellular parasite with a typical coccidian life cycle in which gametogony and oocyst production occur in domestic and wild cats.[83] The parasite differs from other coccidia, however, in that it shows a complete lack of specificity for hosts and tissues during its asexual phase and can infect a wide range of animals including man. The parasite has worldwide distribution and is of both medical and veterinary importance.

Life Cycle. Although the parasite was first identified in 1908,[183] it was not until 1970 that its full life cycle was elucidated.[94,127] Following ingestion of tissue cysts by the definitive feline host, bradyzoites are liberated and enter the epithelium of the small and large intestines in which they undergo asexual reproduction (merogony) passing through five distinct morphological phases before sexual reproduction (gametogeny) begins, mostly in the epithelial cells of the small intestine.[74,153] After fertilization, zygotes develop into oocysts that enter the lumen of the intestine and are shed unsporulated in the feces (Figure 51–3).

The time from ingestion of cysts until oocysts are shed is 3 to 10 days and shedding usually lasts 7 to 21 days.[85] The oocysts are not immediately infectious, requiring 2 to 3 days of further development (sporogony). The sporulated oocyst contains two sporocysts each with four sporozoites. How often a cat is capable of shedding oocysts is not known. Cats can repeat oocyst shedding after reinfection, although the number shed is far less than during the primary infection.[68] Older cats usually do not shed oocysts unless immunocompromised or infected with some other intercurrent disease. When either oocysts or tissue cysts are ingested, sporozoites or bradyzoites enter the tissues of a nonfeline host and transform into the tachyzoite stage. Tachyzoites undergo repeated, rapid multiplication by a process called *endodyogeny* (two progeny form within the parent tachyzoite) until, influenced by the host's immune system, the multiplication rate slows and the tachyzoites transform into bradyzoites. These become surrounded by a cyst wall and remain dormant but infectious in the tissue for long periods of time, sometimes for the life of the host. Bradyzoites transform back into tachyzoites when the cysts are ingested by another host or when the immune system of the current host is suppressed by malnutrition, disease, or medications.

Prevalence in Man and Animals. *Toxoplasma* is widespread among man and animals and is possibly the most widespread and prevalent protozoan parasite on earth,[83] although the reported prevalence varies greatly. It has been estimated that more than 500 million people are infected with it.[75] In the US and the UK, estimated infection rates in man are between 20% to 40%, but are much higher in European countries with rates ranging from 50% to 80%.[72] Infection appears to be more common in warm climates and low-lying areas, probably relating to climatic conditions favoring oocyst sporulation and survival.[95,266,288] In Europe, congenital toxoplasmosis is found in 1% to 6% of newborns and is probably the most serious form of *Toxoplasma* infection. In the US, more than 3,000 babies are born with toxoplasmosis each year; of these, 5% to 15% die, 8% to 10% have brain and ocular lesions, 10% to 13% have visual damage, and the 58% to 72% who are normal at birth later develop active infections.[75] Rates of congenital toxoplasmosis worldwide are estimated at 0.1% to 0.8% of live births.[216] Toxoplasmic encephalitis is now a major opportunistic infection in immunocompromised individuals and it is estimated that 30% of AIDS patients seropositive to *T. gondii* will develop toxoplasmic encephalitis.[59]

In a number of serologic surveys conducted in the US, 25% of 4,871 cats examined were seropositive for *Toxoplasma.*[75] Seropositivity increases with age and varies according to lifestyle, with rates being higher in feral cats than in domestic cats.[67] The prevalence of active shedding of oocysts by cats at any given time is thought to be as low as 1%.[94] This figure can be misleading when considering the potential of cats to spread infection because of the large number of oocysts shed and the ability of oocysts to remain viable for at least 410 days.[288]

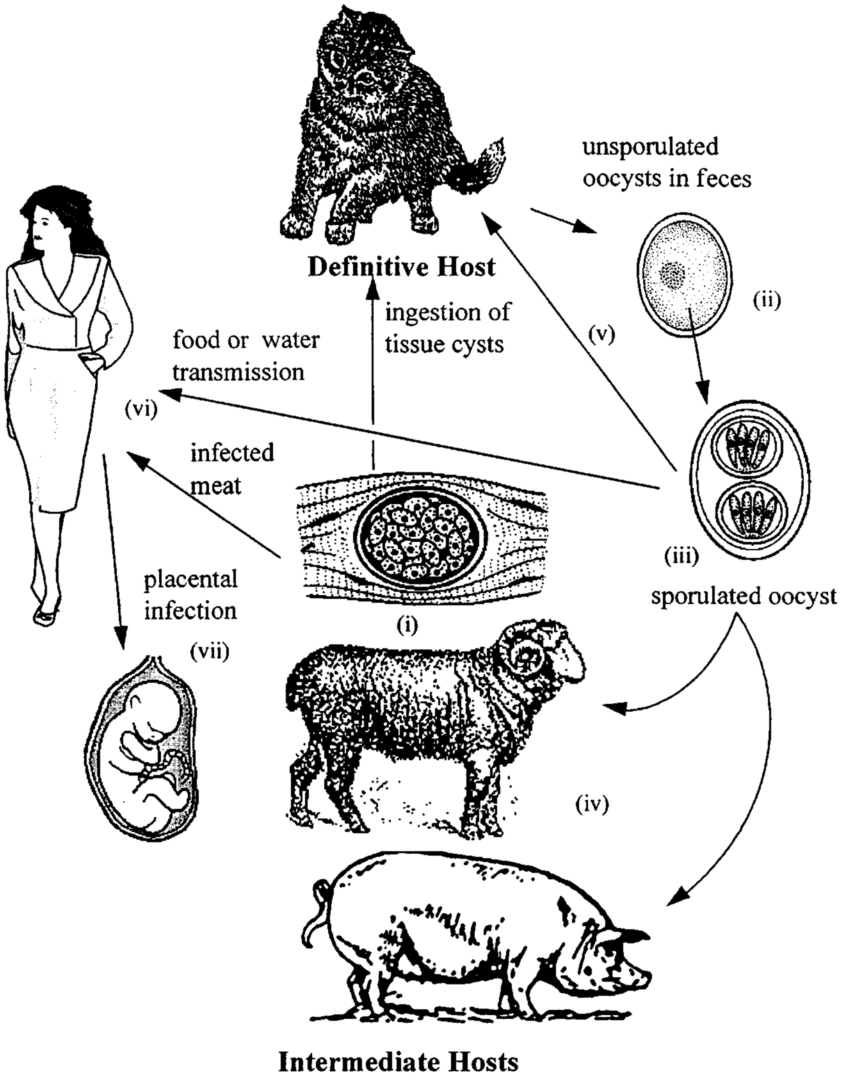

Figure 51–3 Life Cycle of *Toxoplasma gondii.* Following ingestion of tissue cysts (i) by the definitive feline host, liberated bradyzoites transform into tachyzoites and undergo asexual reproduction (merogony) followed by sexual reproduction (gametogony) within epithelial cells of the intestine. After fertilization, unsporulated oocysts (ii) enter the lumen of the intestine and are shed in the feces. After a period of 2 to 3 days, the oocysts sporulate (sporogony) and contain 2 sporocysts each with 4 sporozoites (iii). Ingestion of oocysts by nonfeline hosts (iv) leads to the release of sporozoites, which transform to tachyzoites that undergo rapid multiplication (endodyogeny) producing large numbers of bradyzoites that become surrounded by a cyst wall and remain dormant but infectious. Cats may be infected by ingestion of the sporulated oocysts (v) passed in the feces of other cats. Man becomes infected either by ingestion of the sporulated oocyst through contamination by cat feces or by ingestion of undercooked meat containing tissue cysts (vi). Infection during pregnancy (vii) can lead to congenital infection of the fetus or abortion.

An extensive review has been undertaken on the worldwide prevalence of *Toxoplasma* in food animals based on both serological testing as well as parasite isolation from tissues.[75] In sheep, the prevalence of antibodies increases with age with the level in ewes more than twice that of young lambs. Prevalence appears higher on farms where abortions occur than in normal flocks. Viable *T. gondii* cysts have been recovered from as many as 67% of sheep, mainly from the diaphragm, muscle, and brain. Of all the meat animals, a relatively high percentage of pigs have *Toxoplasma* antibody. Up to 30% of pigs were seropositive and cysts have been isolated from the diaphragm and common cuts of meat. *T. gondii* is rarely isolated from bovine tissues. Serological prevalence varies depending on the serological method used. The actual prevalence may be lower than the reported seroprevalence because of nonspecific cross-reactions with other protozoa, particularly the closely related protozoan parasite, *Neospora caninum* in cattle, dogs, and other animals.[53,76,234]

It has been argued that the estimated levels of infection of lamb, pork, and beef should not be based on serological findings for several reasons. These include strain variation in infectivity, differences in the kinetics of the host's serological response to infection, cross-reactivity, and genetic or other unknown factors imparting resistance to persistent infection in the host.[85]

Epidemiology and Transmission. Humans can acquire toxoplasmosis by ingestion of sporulated oocysts or viable tissue cysts in meat from infected animals. Although a major source of infection of animals is thought to result from contamination of the environment with oocysts shed in cat feces, the extent of human infection resulting from this route is not known. Feces are deposited widely in gardens, fields, playgrounds, buildings, feed troughs, and almost any other location available to cats. The oocysts are easily dispersed by wind and water; by transport hosts such as earthworms, slugs, and insects; by birds or the feet of humans and animals; or indirectly via fomites. They can remain infectious for a year or more if protected from temperature extremes, intense sunlight, and drying. Infection by ingestion of oocysts was the only explanation for the relatively high prevalence of *Toxoplasma* antibody in vegetarians in India.[210]

Although transmission of *Toxoplasma* via contaminated water is a distinct possibility, few reports exist.[20] In contrast, foodborne transmission by ingestion of tissue cysts in raw or undercooked meat from a variety of livestock and game animals has been well documented as a major source of human infection.[75,83] Encysted *T. gondii* are killed at temperatures above 60° C.[77] Among meat-producing animals, pigs, sheep, and goats commonly harbor tissue cysts, whereas cattle, as discussed earlier, appear to be relatively resistant and clear of infection and beef is not generally regarded as an important source of human infection.[83] Epidemiological studies suggest that in many countries ingestion of rare meat may be more important than contact with cat feces.[72] A group of students who ate undercooked hamburgers containing meat of undetermined origin developed acute toxoplasmosis 8 to 13 days later, as did another group of 110 people who ate undercooked meat.[85] Cultural habits are an important factor in the epidemiology. Several outbreaks have been associated with specific cultural preference for undercooked meat rather than mishandling or accidental undercooking. In Russia, significantly more *Toxoplasma* seropositive people were identified among women who tasted raw minced meat during cooking than among those who did not taste raw meat.[170] In France, 84% of French women have antibodies to *T. gondii* compared with 30% of women in the UK and US. The higher incidence in French women may be due to the habit of eating raw or undercooked meat. In Hawaii, a higher prevalence of infection was found among Hawaiians and Filipinos who ate raw meat (including pork) than among Caucasians and Japanese who thoroughly cooked meat.[264] In France, 204 children became infected while they were hospitalized and fed meals of very rare or raw meat.[62] Milk from infected goats has also been implicated as a source of infection.[211,225]

Occupational risks of infection may include certain farming practices, and pregnant women and other people in special risk groups should avoid contact with sheep at lambing time.[36]

Cats become infected by ingesting tissues from animals harboring cysts of *Toxoplasma* containing cystozoites or bradyzoites, by ingesting tachyzoites present in the tissues of acutely infected prey animals such as rodents, or by ingesting oocysts shed in the feces of other cats.

As with human vegetarians, herbivores must acquire *Toxoplasma* infection from oocysts. The prevalence of *Toxoplasma* antibody in herbivores such as cattle and sheep is a good indicator of the distribution of cat feces in the environment.

Clinical Signs. Clinical signs of toxoplasmosis can be highly variable because *Toxoplasma* can infect virtually every organ in the body. In humans, toxoplasmosis usually is asymptomatic or associated with mild symptoms, often only characterized by lymphadenopathy involving the posterior cervical lymph nodes. Acute infections can cause anemia, dermomyositis, encephalitis, enteritis, fever, hepatitis, lymphadenitis, myocarditis, placentitis, pneumonitis, retinochoroiditis, skeletal myositis, tynosynovitis, tonsillitis, and vasculitis.[83] The interval from exposure to clinical illness is quite variable. Generally, clinical signs are manifested from a week to a month after exposure. Duration, severity, and outcome generally vary according to the immunological state of the host. In immunocompromised individuals (eg, AIDS patients), *T. gondii* infections can be severe with cerebral involvement.[137] Perhaps the greatest significance is as a cause of congenital infection and abortion in pregnant women.[70] The fetus is thought to become infected via the placenta as a consequence of parasitemia in the mother. Usually the earlier in pregnancy infection is acquired, the greater the extent of lesions in the fetus will be. In animals, clinical signs are not usually seen in the cat but can be severe in intermediate hosts. In sheep, abortion, stillbirth, or birth of weak lambs may occur depending on when infection of the pregnant ewes occurs. Infection in mid pregnancy (60 to 90 days) usually results in abortion.[36] Ewes infected during the later stages of pregnancy (after 110 days), can lead to stillborn or weak lambs at full term.

Methods of Detection. Serological tests used in the diagnosis of toxoplasmosis include the Sabin and Feldman Dye test (DT),[224] complement fixation test (CFT), indirect fluorescent antibody test (IFAT),[42] ELISA,[260] and commercially available indirect hemagglutination test (IHA), and latex agglutination test (LAT).

Clinical signs and pathological changes in placenta and aborted fetuses of ruminants are not pathognomonic for toxoplasmosis, and detection of *Toxoplasma* tachyzoites by histological methods is not always easy, especially in autolyzed material. Impression smears stained with Giemsa or Romanowsky[69] or PAS[71] may allow identification of tachyzoites or tissue cysts. Diagnosis may be confirmed by isolation of viable parasites by mouse inoculation with tachyzoites or cysts or by demonstration of parasite stages by immunohistochemical methods.

Recently diagnostic methods based on detection of *T. gondii*-specific DNA by PCR have been developed. These have been based upon the p30 gene and can detect a single organism in the presence of a million host cells.[226] This PCR has also been applied to tissues from sheep (brain, amnion/chorion, peritoneal fluid, and cotyledons).[277] Other PCRs have been developed based on sequences of ribosomal DNA[113] and the B1 gene.[140] A study comparing the p30 and the B1 PCRs found that the B1 PCR was more sensitive, it gave fewer false negatives, and the results correlated closely with conventional mouse inoculation methods.[270]

Prevention and Control. Any measures that reduce or eliminate contamination of the environment with oocysts from cat feces will help prevent toxoplasmosis. Domestic cats should be prevented from hunting birds and rodents. They should be fed thoroughly cooked food (dry or canned). Litter trays should be used in the home and emptied daily. Gardeners handling soil should wear gloves and wash their hands thoroughly before eating or handling food. Cats on farms should be prevented from entering feed-storage facilities and animal quarters.

All meat should be cooked thoroughly before eating. Cooking at 60° C or higher for 3½ minutes or longer renders *Toxoplasma* cysts noninfectious.[77] It is important to know the actual temperature in the core of the meat, not just the surface temperature. Microwave ovens should not be used for initial cooking because of the uneven distribution of heat resulting in hot and cold spots.[85] Freezing to –20° C also kills some strains of *Toxoplasma* but is less dependable than cooking. Salting, curing, and pickling also kill cysts present in meat.[281]

Irradiation of meat at 0.5 kGy or greater renders *Toxoplasma* cysts noninfectious.[73]

Finally, water from lakes, ponds, streams, or other untreated sources should be boiled before drinking or being used to wash food.

Conclusion. Infection with *Toxoplasma gondii* is one of the most common of parasitic infections of man and other warm-blooded animals. Foodborne transmission through ingestion of raw or undercooked meat or other animal produce such as milk is well documented. Adequate cooking kills the organism as does pasteurization. Contact with cat feces should be avoided, especially in the immunocompromised and in women during pregnancy. Contaminated water presents a risk and steps should be taken wherever possible to avoid consumption of untreated drinking water.

51.3 FLAGELLATE PROTOZOA (MASTIGOPHORA)

51.3.1 *Giardia*

History. *Giardia* infections are frequently overlooked in domestic animals despite the isolation of the protozoan from a variety of mammalian, avian, reptilian, amphibian, and fish hosts. The host specificity of *Giardia* is still not known and the zoonotic potential of animal infection is the subject of much research. For a long time it was considered that

Next Page

Giardia species were host-specific; this resulted in the description of more than 40 species based on the host species in which they were found. This assumption is not universally accepted, however, and current thought is that there are just three structural types or species (Figure 51–4A).

The species affecting man and the majority of domestic animals is referred to as *Giardia duodenalis* and the names *G. intestinalis*, *G. lamblia*, and *Lamblia intestinalis* are synonymous. The other morphologically different species are *G. muris* identified in rodents, birds, and reptiles and *G. agilis* from amphibians.

Biochemical and immunological differences in *Giardia* isolated from humans suggest that there is a great deal of heterogeneity within these strains, while at the same time relatively close relationships exist between certain human and animal strains.[256]

Life Cycle. *Giardia* are flagellate protozoans normally found adherent to epithelial surfaces of the small intestine, especially the middle to lower areas of the villi. The life cycle is simple and direct, the trophozoite stage (motile forms) dividing by binary fission to produce further trophozoites. Species variation exists in the size of the trophozoite and in the shape and size of the median bodies (Figure 51–4A). Intermittently, trophozoites form resistant cyst stages that pass out in the feces of the host.[3] The life cycle is shown in Figure 51–5.

Prevalence in Man and Animals. Infection with *Giardia intestinalis* has been increasingly recognized over the last decade and has been reported as the most common intestinal protozoan parasite in the world in man.[269] Very high prevalence rates of between 20% and 60% are common, particularly in children in developing countries.[28,79,82,107,128,165,171,172,175]

The existence of *Giardia* in domestic animals has been known for many years, but during that time little information has become available on prevalence, pathogenicity, and the disease caused by these parasites in their hosts. *Giardia* has been reported in cattle, sheep, goats, horses, dogs, cats, rodents, and psittacines. Based on limited investigations that involved screening for fecal cysts, the incidence of these parasites varies but can be assumed to be higher in some species than has been reported. Studies in Canada[34] indicate that 18% of sheep and 10% of cattle were infected. In a study conducted in the US, a 100% infection rate was found in young diarrheic calves on two farms.[285] In the UK, nearly 70% of a flock of lambs were infected with *Giardia*, although the presence of the organism was not necessarily associated with clinical signs of disease.[251] Recent studies in cattle described high levels (15% to 32%) of natural prevalence, with the highest level during the winter months.[221] A survey of dogs attending a charity animal hospital in London[247] showed an overall prevalence of infection of 15% with the highest prevalence (30%) in dogs less than 12 months of age. Studies conducted in the US found between 12%[145] and in the US and Canada 1% to 68% of dogs to be infected with *Giardia*.[121] In aviary birds, *Giardia* is frequently encountered in psittacines such as cockatiels, budgerigars, and lovebirds causing enteropathy, weight loss, and death.[97]

Epidemiology and Transmission. Transmission of the dormant, environmentally resistant cyst stage is via the fecal-oral route through contaminated water, contaminated food, or person-to-person, animal-to-animal contact. Cysts can remain infectious for several months under moist and cool conditions, but lose infectivity under dry and hot conditions.

Infection with *Giardia intestinalis* generally is associated with conditions of poor hygiene and sanitation, including poor control of water quality.[15,86,166,209,269] Infection is common among children who attend day-care centers but is also associated with travel.[15,26,99,138,269]

Reports of foodborne transmission of *Giardia* have been made only occasionally. Cysts have been detected in salad, fruit, and other food items.[15] Outbreaks of giardiasis have occurred following the consumption of salmon and cream cheese dip,[191] noodle salad,[197] sandwiches,[278] and fruit salad.[204] Waterborne outbreaks have been reported in the US and the UK.[133] In the former, *Giardia* has been identified more often than any other pathogen in waterborne outbreaks that result in illness. From 1971 to 1985, *Giardia* was identified in 92 of 502 reported waterborne outbreaks, resulting in 24,000 cases of illness.[55] Most cases result from consumption of water intended for drinking or for domestic purposes as well as from consumption from other nonpotable sources by swimmers, divers, hikers, and campers. Human infection in the US has been reported from drinking water contaminated with *Giardia* thought to have originated from beavers.[81]

Because *Giardia* is so widespread among domestic and wild-animal hosts, its zoonotic potential has aroused interest and concern. The occurrence of direct animal-to-human transmission of giardiasis remains controversial. The close association between

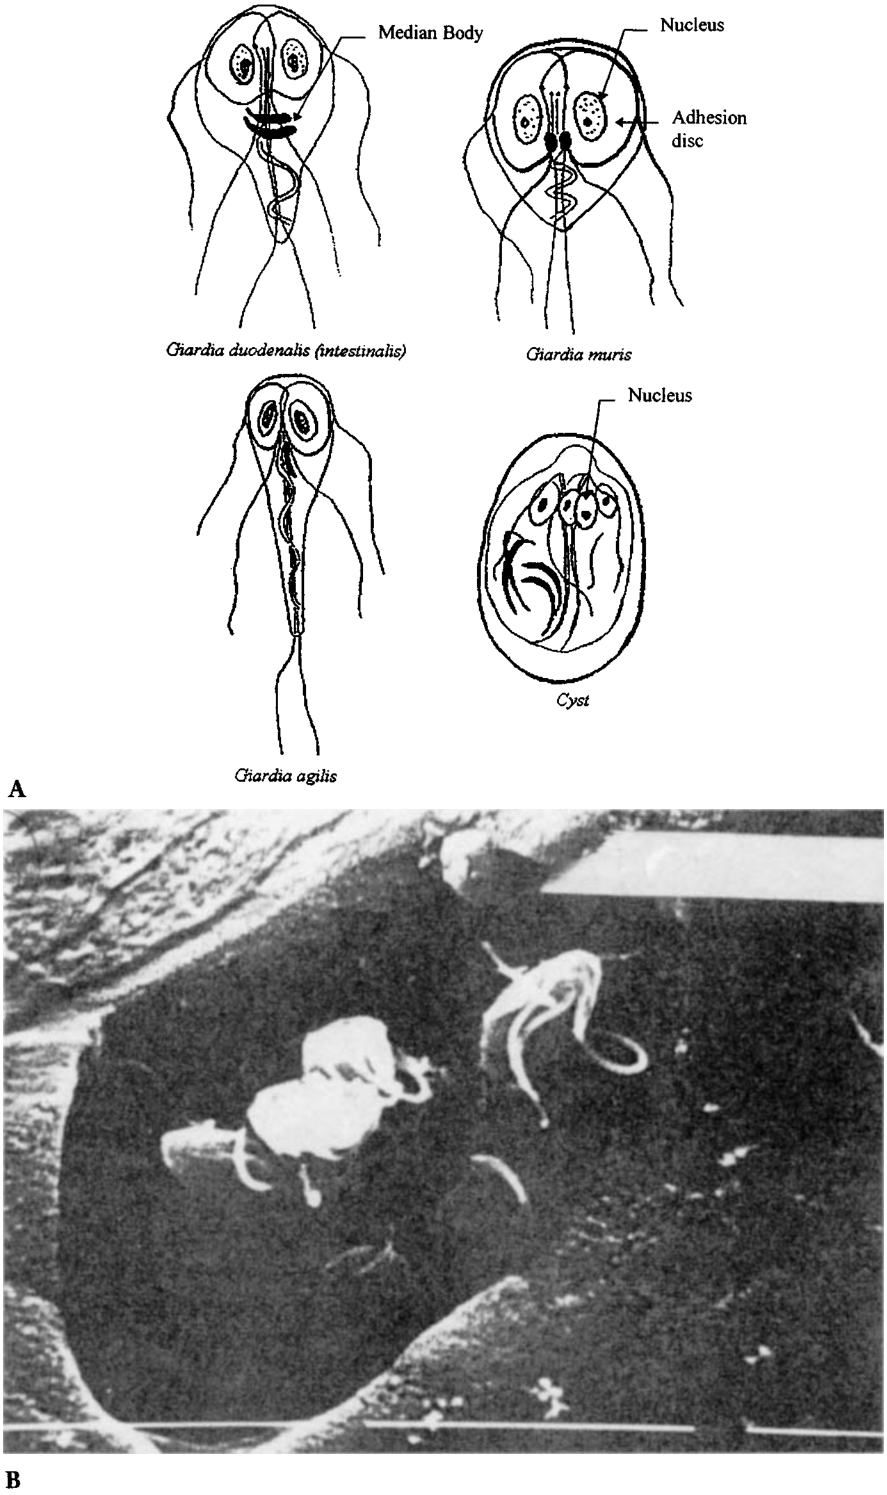

Figure 51–4 Trophozoites of *Giardia*. **A**, Three morphologically distinct species of *Giardia* are recognized and distinguished by the shape of the median body (labeled). In *Giardia duodenalis*, the species infecting domestic mammals including man, the median bodies are in the shape of a "claw hammer." *Source:* Reprinted with permission from M.A. Taylor, Waterborne Parasites: A Veterinary Perspective, *Health and Hygiene*, Vol. 14, p. 56, © 1993, Royal Institute of Public Health and Hygiene. **B**, scanning electron micrograph of trophozoites of *Giardia intestinalis* (small intestine lamb). *Source:* Copyright © 1999, Ministry of Agriculture, Fisheries and Food, U.K.

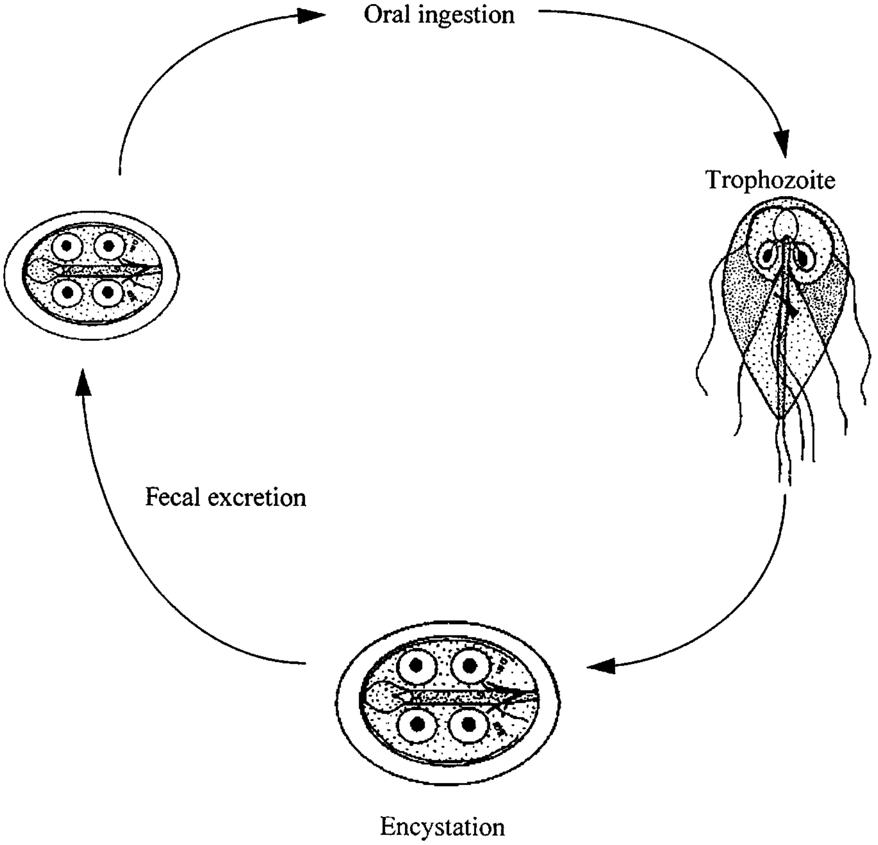

Figure 51–5 Life Cycle of *Giardia intestinalis (duodenalis)*. Trophozoites of *Giardia* are normally found adherent to the epithelial surface of the small intestine where they reproduce by binary fission to produce further trophozoites. Intermittently, trophozoites encyst and are passed out in the feces until ingested by a new host.

humans and companion animals provides opportunity for transmission but unequivocal evidence is lacking. Although anecdotal information indicates that dogs, especially puppies, could serve as sources of human infection, there is no documented evidence of dog-to-human transmission.[121] Cats also might be a source of human infection, but reported cases of feline giardiasis are rare and sometimes circumstantial.[121] Based on reports of giardiasis in hikers and campers who obtained drinking water from untreated surface waters in areas in which few humans are present, wild animals have been suspect reservoir hosts. Aquatic mammals (beavers and muskrats) as well as such aquatic birds as egrets and green herons have been found infected with *Giardia*.[121]

In animals, limited epidemiological studies suggest that direct animal-to-animal contact and fecal soiling is the most likely method of transmission, although water is also likely. Other wild animals may act as reservoirs of infection. Infection in a calf has been established with a human isolate.[221] The role of farm animals in the overall epidemiology of human giardiasis has yet to be investigated.

Clinical Signs. The most-prominent initial signs of giardiasis in man include nausea, inappetence, discomfort in the upper intestine, and fatigue, followed by bursts of foul-smelling watery diarrhea, flatulence, and abdominal distention, usually lasting only a few days.[173,279] Occasionally, this acute stage can last for months, causing malabsorption, weight loss, and debilitation. Chronic infection is marked by recurrent brief episodes or, to a lesser extent, persistent episodes of foul-smelling loose feces, flatulence, and abdominal distention. Lactose intolerance, common during active infection, may persist for a period thereafter. Mortality has seldom been reported.

Giardia infections in many species of animals are often asymptomatic. When disease does occur, the signs often include chronic, pasty diarrhea, weight loss, lethargy, and failure to thrive. The diarrhea may be continuous or intermittent.

Methods of Detection. Diagnosis is based on identification of cysts or trophozoites in feces, or trophozoites in duodenal aspirates or biopsies. Most diagnoses can be made by fecal examination. *Giardia* cysts can be detected in feces by a number of methods. Traditional methods of identification of giardiasis involve direct examination of fecal smears or fecal concentration by formalin-ethyl acetate or zinc sulphate methods and subsequent microscopic examination.[3] It is generally recommended that three consecutive samples are examined as cysts are excreted intermittently,[144] and a single sample identifies only 50% to 75% of positive cases.[3,124] Recent developments include the use of fluorogenic dyes such as fluorescein diacetate, which is taken up by viable cysts, and propidium iodide, which is taken up by nonviable cysts.[238]

Several immunoassays are available commercially. These involve either the identification of cysts by IF[245] or detection of *Giardia* specific antigen by ELISA.[111,181,262]

The use of PCR to amplify target DNA has produced a sensitive and specific assay for *Giardia* based on the detection of the giardin gene (*Giardia*-specific genomic DNA).[35] In addition, the PCR technique is reported to be able to distinguish between pathogenic and nonpathogenic *Giardia* strains[160] and between live and dead cysts by measuring PCR product from giardin mRNA.[161]

Prevention and Control. Control of giardiasis is based on good personal hygiene, proper sanitation, and treatment of drinking water. Because virtually all surface waters can potentially be exposed to *Giardia* contamination from human or animal sources, all *Giardia* cysts should be regarded as potentially infective for humans. Slow sand filtration, filtration with diatomaccous earth, or coagulation-filtration are the methods most commonly used by the water supply industries and usually remove 99% or more of the *Giardia* cysts.[131] Chemical disinfectants such as chlorine, chlorine dioxide, chloramine, and ozone can further reduce the number of infectious cysts in drinking water,[131] but their effectiveness may be reduced by changes in pH, water temperature, turbidity, concentration of disinfectant, and contact time. A combination of filtration and disinfection is often used to best effect.

Conclusion. As with cryptosporidiosis, foodborne infections with *Giardia* are relatively uncommon and the main risk of transmission to man appears to be through foreign travel, especially to underdeveloped countries, or via contamination of drinking water. Implementation of water monitoring and improved treatment facilities should help reduce the risks of waterborne transmission. However, current techniques for the species identification, enumeration, and viability assessment of waterborne cysts are imprecise, which makes the interpretation of the public health significance of detected cysts difficult.

51.4 AMOEBOID PROTOZOA (SARCODINA)

51.4.1 *Entamoeba*

History. *Entamoeba histolytica* is one of six parasitic amoebae of the genus *Entamoeba* known to infect humans.[29] It has also been recorded in cattle, pigs, dogs, cats, and monkeys.[153] In man, the primary route of transmission is from human to human by the fecal-oral route, usually associated with poor hygiene or poor water quality. Infections with *E. histolytica* occur worldwide but are more prevalent in the tropics. There are two morphologically identical forms of *E. histolytica,* one nonpathogenic and the other pathogenic.[29]

Life Cycle. Trophozoites in the intestine, which vary between 12 μm to 60 μm in diameter, divide by binary fission. Transmission occurs when the trophozoites round up, become smaller, and form a cyst (8.5 μm to 19 μm). Nonpathogenic forms of the organism normally live in the lumen of the large intestine. Pathogenic forms invade the mucosa, causing ulceration and dysentery. From there they may be carried via the portal system to the liver and other organs where large abscesses may form (see Figure 51–6).

Prevalence in Man and Animals. It has been estimated that approximately 480 million people, or 12% of the world's population, are infected and that annual mortality is 40,000 to 110,000 people.[115] About 10% of those infected every year have clinical symptoms.[265] Five percent of the US population were estimated to be infected, but its prevalence appeared to be declining.[159]

The incidence in animals is unknown. *Entamoeba histolytica* has been found in naturally infected monkeys of many species throughout the world. Infection in dogs has only been reported sporadically and often through human contacts. Natural infections are apparently rare in pigs and have to be differ-

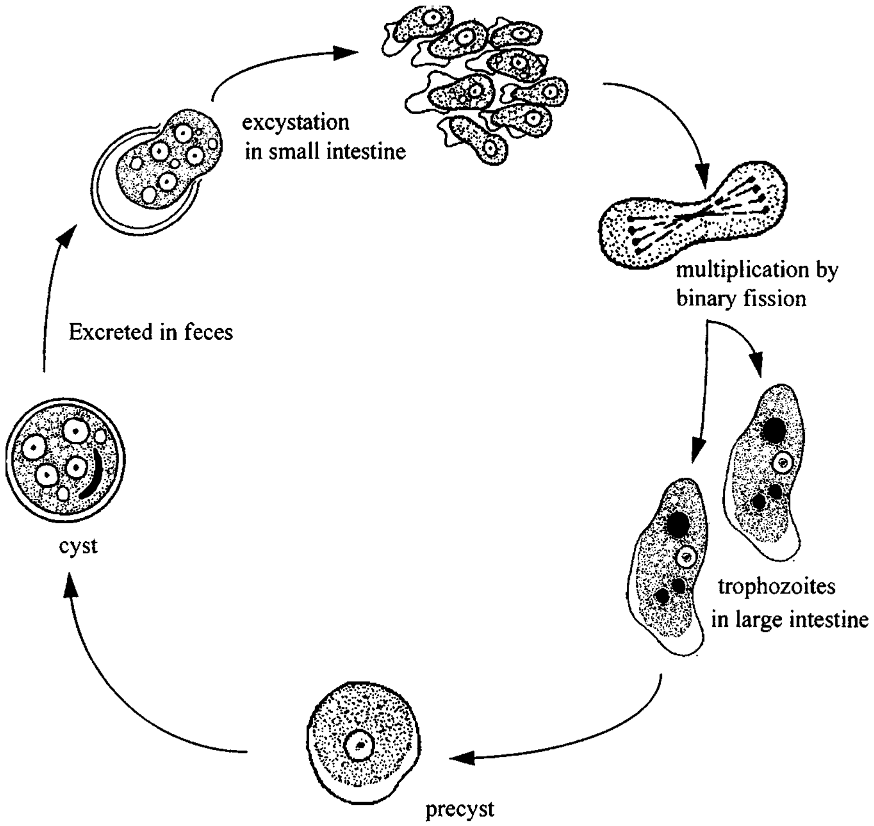

Figure 51–6 Life Cycle of *Entamoeba histolytica.* Trophozoites in the large intestine divide by binary fission to produce further trophozoites. Some trophozoites round up, become smaller, and form cysts, each containing 4 small amoebae, which are passed out in the feces. Once ingested by a new host, excystation occurs in the small intestine releasing the young amoebae, which divide so that each cyst produces 8 small amoebae. *Source:* Adapted from an Atlas of Protozoan Parasites in Animal Tissues, *Agriculture Handbook No. 65,* p. 10, U.S. Department of Agriculture.

entiated from other species that occur in the pig, notably *Entamoeba suis* (*E. polecki*) and *Iodamoeba buetschlii.*[153]

Epidemiology and Transmission. Ingestion of food and drink contaminated with *E. histolytica* cysts from human feces and direct fecal-oral contact are the most common means of infection. Transmission from human to human by the fecal-oral route is usually associated with poor hygiene or poor water quality. Cysts can be introduced into the mouth by soiled hands of food handlers, family members, hospital personnel, and other close personal contacts, by food contamination via flies, and by water contaminated with sewage. Transmission of *E. histolytica* by water is common in third-world countries where much of the drinking water is untreated. The use of human feces for fertilizer is also an important source of infection.[29] Recognized high-risk groups include travelers, immigrants, migrant workers, and immunocompromised individuals and male homosexuals. *E. histolytica* has been found in as many as 32% of homosexual men in North America.[6] Almost all of the strains of *E. histolytica* isolated from AIDS patients have been classified as nonpathogenic.[6,32,108.,276]

Despite documentation of naturally infected nonhuman primates and experimental infection of such other animals as cats and dogs with *E. histolytica,* human infection from any animal source has not been documented. However, knowledge that *E. histolytica* can infect animal hosts serves as warning that, under the right conditions, animals might be a source of *E. histolytica* infecting humans.

Clinical Signs. Most human infections are asymptomatic, with the parasite acting as a harmless commensal organism in as many as 90% of those infected.[61,115] Many asymptomatic individuals never become symptomatic, and usually excrete cysts in the feces for only a short period of time. About 10% of individuals infected with *Entamoeba* *histolytica* have clinical symptoms associated with tropical dysentery with bloody or mucoid diarrhea. Symptoms can range from mild bowel discomfort to diarrhea or dysentery with or without blood and mucus. Infections can last from a few days to several months. The symptoms associated with invasive intestinal amoebiasis are usually nonspecific and can produce ulcerative lesions in such extraintestinal sites as the liver and the skin or even the brain. Amoebic colitis is associated with ulceration of the colon.[47] If ulceration with perforation occurs, the cecum is the area normally involved.[135]

Infections in animals are generally asymptomatic although liver infections may occur in some species of monkey.

Methods of Detection. Trophozoites of *E. histolytica* have a spherical or oval shape (12 μm to 60 μm in diameter) with a large, single nucleus that contains a central karyosome (intranuclear body) and minute, irregularly shaped masses of peripheral chromatin. Cytoplasm generally contains vacuoles and sometimes extends as irregular fingerlike projections (pseudopods) from the margin. Mature cysts often have four, rarely eight, nuclei. Trophozoites and cysts can be stained with iodine in wet mount preparations or with PAS, trichrome, or iron hematoxylin. The organisms can also be cultured in a number of media including Boeck and Drbohlav's, Dobell and Laidlaw's, TYI-S-33,[64] and Robinson's medium.[63] Serological tests that have been evaluated for the diagnosis of *E. histolytica* infections include ELISA,[186] latex agglutination, complement fixation;[158] and indirect hemagglutination.[23] A number of PCR methods have also been used to detect *E. histolytica* in clinical samples.[2,49,219,248] Isoenzyme markers can be used to differentiate the two forms, but there is some debate as to whether the two types represent different species or if they can change from one type to another under certain circumstances.[29]

Prevention and Control. Prevention is by elimination of fecal contamination of food and water. Good personal hygiene, especially thorough washing of hands by food handlers, good sanitation, and high-quality water treatment are essential for preventing transmission.

Conclusion. Although waterborne transmission of *Entamoeba histolytica* occurs throughout third-world countries, and the prevalence of infection remains relatively high, the incidence in industrialized societies appears to be decreasing. The main risk of infection is therefore from drinking untreated and fecally contaminated water.

51.5 BLASTOCYSTA

51.5.1 *Blastocystis*

History. *Blastocystis* was described for many years as a yeast but is now considered to be a protozoan in the subphylum Blastocysta.[134] The organism is found in the intestinal tract of man and in many animals including monkeys, pigs, birds, rodents, snakes, and invertebrates. Infection generally is asymptomatic but it is becoming increasingly associated with gastrointestinal disease in man.[290]

Life Cycle. The life cycle first described for this organism was complex, involving binary fission of a binucleate stage followed by autogamy (sexual reproduction) to form primary cysts. These cysts were thought to produce spores by multiple budding leading to the production of resistant secondary cysts. In this life cycle, asexual merogony and sporogony also were described.[5] It was proposed later that only asexual reproduction occurred, with division occurring by at least four different modes described as binary fission, plasmotomy, endodyogeny, and merogony.[290] Further studies involving electron microscopy have failed to reveal endodyogeny, merogony, or sporogony. Binary fission is therefore the only proven method of reproduction at the present time.[24] The predominent form present in the human colon is a small nonvacuolated cell. As the nonvacuolated form passes through the colon, a multivacuolar form develops, which leads to the ultimate formation of a cyst that is passed out in the feces (Figure 51–7).

Prevalence in Man and Animals. Reports of the prevalence of *Blastocystis* are very variable. Studies in man show varying levels of infection with *B. hominis* in both healthy patients and patients with diarrhea.[148,164,185] Infection appears to be more common in adults than children.[66,142,206]

Blastocystis has been reported in a wide range of animals. In mammals it has been reported in a pig-tailed macaque,[167] monkeys,[286] and pigs.[33,192] The pathogenicity of *Blastocystis* in pigs is uncertain. Cross-transmission studies have indicated a low host specificity for *Blastocystis*,[192] and it is likely that the parasite will be found in other farm livestock.

The organism has also been reported in chickens,[18,286] ducks,[193] partridge and pheasants,[252] and reptiles.[255]

Epidemiology and Transmission. It is generally presumed that *B. hominis* is transmitted by the fe-

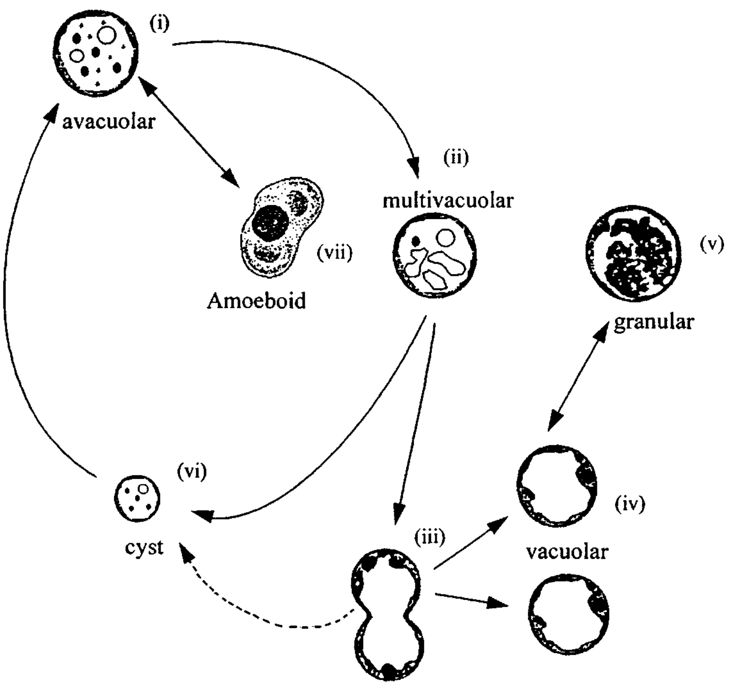

Figure 51–7 Life Cycle of *Blastocystis hominis.* Various life cycles have been described for *Blastocystis hominis;* the following description is that proposed by Boreham and Stenzel. Small nonvacuolated cells (i) present in the colon develop into multivacuolar forms (ii), which can then develop into resistant cyst stages (vi) and pass out in the feces. The typical vacuolar form (iii) arises from the multivacuolar form by coalescence of the smaller vacuoles and divides by binary fission. Under adverse conditions, the vacuolar form may transform to the granular form (v) or may develop into a cyst. It is thought that an amoeboid form (vii) may, on occasions, arise from the avacuolar form. Infection of a new host probably occurs following ingestion of the cyst form, although it may be that the vacuolar form, which appears in feces, may also be infective. *Source:* Adapted with permission from P.F.L. Boreham and D.J. Stenzel, *Blastocystis in Humans and Animals: Morphology, Biology, and Epizootiology,* Advances in Parasitology, Vol. 32, p. 40, © 1993, Academic Press, Inc.

cal-oral route in a similar manner to other enteric protozoa.[101] Familial transmission[114] and transmission within institutes for the mentally retarded[287] have been reported. Waterborne and foodborne transmission are possible routes of infection[101] but have not been investigated. Infections in man have been linked with foreign travel.[66,142,233] In one study, 44% of patients infected with *B. hominis* had a history of exposure to pets or farm animals.[66]

Clinical Signs. It is still unclear whether *Blastocystis* is a pathogen or commensal. Symptoms usually associated with human infection with *B. hominis* include diarrhea, abdominal discomfort, anorexia, flatulence, and other nonspecific gastrointestinal effects. It may be the case that the organism is pathogenic only under specific conditions such as immunosuppression, poor nutrition, or concurrent infections.[24]

Studies in several species of animals suggest that *Blastocystis* is not pathogenic to the host. Large numbers of *Blastocystis* were present in diarrheic pigs sampled from four farms in the UK but no evidence was found to suggest that *Blastocystis* had a pathogenic role.[33] Similar observations were made in partridges in the UK.[252] Both studies suggested that diarrhea may produce conditions suitable for growth of *Blastocystis* rather than the reverse.

Methods of Detection. In fecal samples, *B. hominis* is brightly refractile, of widely variable diameter (4 µm to 15 µm), with a thin band of peripheral cytoplasm surrounding a central vacuole. In severe infections, an amoeboid form may be seen.[290] Diagnosis is based on microscopic identification of characteristic refractile, pleomorphic forms either using bright field optics or by differential interface contrast optics. Fecal smears can be heat fixed or gluteraldehyde fixed and stained with Giemsa, trichrome, or iron hematoxylin. The organism can be cultured successfully in Boeck Drbohlav's, Dobell and Laidlaw's medium, or Robinson's medium.[252] Limited immunological methods of diagnosis have been developed. An immunofluorescent staining method using rabbit antiserum raised to whole *B. hominis* antigen has been described.[290]

Prevention and Control. Prevention is as with other intestinal protozoa—through good hygiene, especially thorough washing of hands by food handlers, and good sanitation aimed at preventing transmission.

Conclusion. *Blastocystis* is increasingly reported as an intestinal infection of man, but it is not clear whether it acts as a pathogen. Transmission is by the fecal-oral route and waterborne and foodborne transmission are potential routes of infection, but have not as yet been investigated to any great extent.

51.6 CILATED PROTOZOA (CILOPHORA)

51.6.1 *Balantidium*

History. *Balantidium coli* occurs in man, other primates, pigs, and occasionally in the dog, rat, and ruminants. The pig appears to be the primary host, and in it *B. coli* generally is regarded as a commensal of the large intestine where it lives on starch, ingesta, and bacteria.[153] It has only rarely been reported as a foodborne or waterborne zoonotic.

Life Cycle. Trophozoites in the lumen or tissues multiply by binary fission and under certain conditions transform into cysts that pass from the body in the feces (Figure 51–8A).

Prevalence in Man and Animals. The organism is found worldwide in humans, but the prevalence of disease based primarily on case reports appears low. Only 722 cases were reported worldwide by 1960 and few have been reported since then. The low prevalence may be in part a combination of lack of recognition of the organism and inappropriate diagnostic procedures.

Epidemiology and Transmission. Transmission via the fecal-oral route is from human to human and possibly from pigs or rats to humans. Transmission is facilitated in confined environments in which hygiene is poor. The cyst form is the source of infection and cysts can remain viable for days or weeks in moist pig feces.

Flies are possible mechanical vectors. Although pigs have been implicated as a major source of human infection, their role is still a source of controversy. In a review of the literature, more than 50% of the persons with balantidiasis reported contact with pigs.[268] In one case, a family claimed that infection followed ingestion of raw pork sausage. Surveys of fecal samples collected throughout New Guinea revealed prevalence rates of infection with *Balantidium* as high as 29% in some areas in which people lived in intimate contact with pigs. A waterborne outbreak implicating pigs as the source of infection has been reported.[267]

Balantidium infection in monkeys and primates is normally an endemic infection maintained by the animals themselves.

Clinical Signs. In man, *B. coli* is a widespread asymptomatic commensal but may on occasions produce superficial to deep ulcers that result in intermittent diarrhea or dysentery. Clinical infections resemble amoebiasis with diarrhea, abdominal pain, nausea, vomiting, and tenesmus. Sometimes the diarrhea contains mucus, blood, or pus. Chronic infections are characterized by alternate episodes of diarrhea and constipation with cramps, abdominal pain, and tenesmus. Rare complications include perforation of the bowel wall and extraintestinal infection of the liver, vagina, ureter, and bladder.

B. coli is also a widespread asymptomatic commensal in the intestine of pigs, where it may invade the mucosa and cause ulceration and mild to severe diarrhea.[103] Severe clinical disease also has been reported for nonhuman primates, especially the great apes.

Methods of Detection. *Balantidium* are large, highly motile ciliated protozoa and can be readily identified in wet mount preparations stained with iodine in which they appear orange with black starch granules (Figure 51–8B). The trophozoites are oval with a slightly pointed anterior end, have a thin membrane covered with cilia, have foamy cytoplasm with a large macronucleus and a tiny micronucleus, and measure about 40 μm to 80 μm by 25 μm to 45 μm. Cysts are round to oval, are surrounded by a thick wall, contain a macro- and micronucleus, and measure about 40 μm to 65 μm.

In fresh fecal smears, the organism can be stained with trichrome or iron hematoxylin. Cultural isolation is not usually necessary, although the organism has been successfully cultured in gastrin mucin media.[146]

Prevention and Control. Prevention is the same as for amoebiasis. Under severe environmental conditions, water thought to be contaminated should be boiled before use.

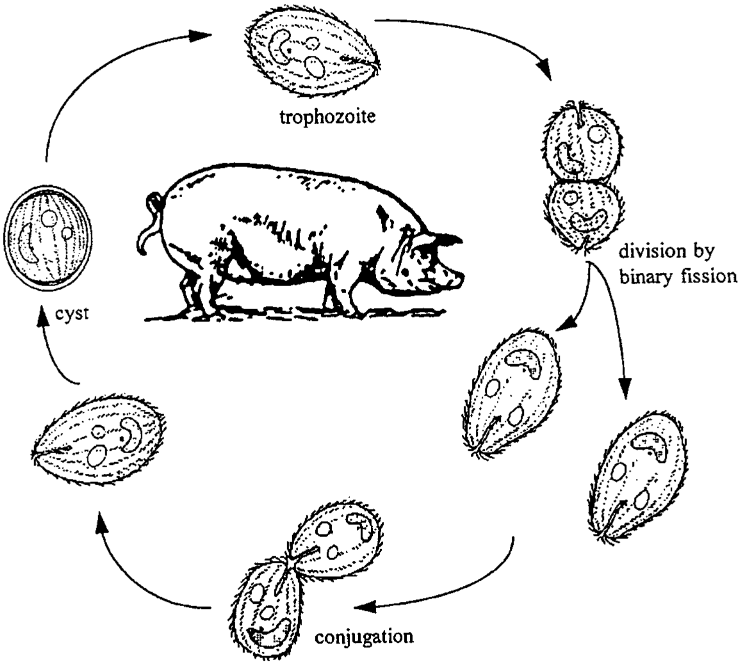

Figure 51–8A Life Cycle of *Balantidium coli.* Trophozoites present in the lumen or tissues of the large intestine divide by binary fission to produce further trophozoites. Conjugation resulting in exchange of genetic material has been observed. Under certain conditions trophozoites transform into cysts and are passed out in the feces.

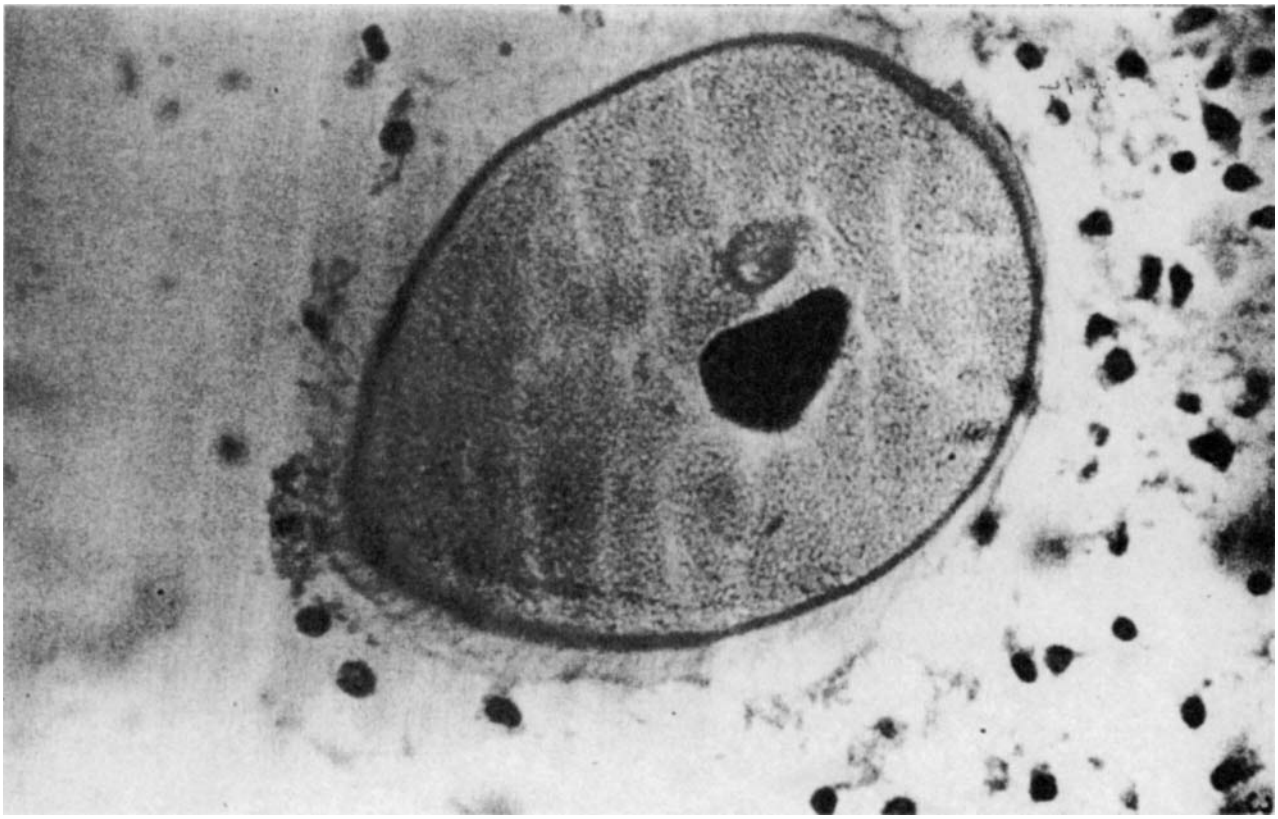

Figure 51–8B Trophozoite of *Balantidium coli* [photographed at x640 Haematoxylin-Eosin stain]. The large macronucleus is clearly visible. *Source:* Copyright © 1999, Ministry of Agriculture, Fisheries and Food, U.K.

Conclusion. *Balantidium* infections in man are relatively infrequent and the epidemiology is not fully understood. Infection is likely to be due to contamination of water or uncooked vegetables. The organism is primarily a parasite of pigs and it is thought that pigs act as a reservoir of infection for man.

51.7 MICROSPORA

51.7.1 Microsporidia

History. "Microsporidia" is a nontaxonomic term used to describe organisms in the phylum Microspora, which contains over 100 genera and 1,000 species that are ubiquitous in nature and infect a wide range of vertebrate and invertebrate hosts. Five genera have been implicated in human disease and infections have been documented from nonmammalian genera, suggesting some lack of host specificity. *Microsporidia* are obligate intracellular parasites that have been found in every major group of animals, and have been reported in man and a wide range of domestic animals and wildlife including reptiles, amphibians, and fish.[39] In man, they are gaining attention as opportunistic pathogens in AIDS patients.[90,147,188,189,207,227,231] At least 5 genera are known to infect and produce disease in man: *Encephalitozoon, Enterocytozoon, Nosema, Pleistophora*, and *Septata*.[30,120]

Life Cycle. The infective stages are resistant spores, which can survive in moist, cool conditions for 1 or more years. Spores consist of an infective agent (sporoplasm) and an extrusion apparatus consisting of a polar tube attached to an anchoring disc (polar sac). When spores are ingested by a new host, the polar tube is everted and attaches to a host cell, and the sporoplasm is inoculated into the host cell cytoplasm. This is followed by a phase of multiple fission (merogony) leading to sporogony resulting in the production of spores (Figures 51–9 and 51–10).

Prevalence in Man and Animals. In humans, microsporidia have been found particularly in patients with immunosuppression such as AIDS patients. Studies from patients with AIDS enteropathy showed 30% to 35% to carry microsporidia.[147,246] The two most common intestinal microsporidia in patients with AIDS are *Enterocytozoon bieneusi* and *Septata intestinalis*.[31] As medical practitioners become aware of microsporidia, they are increasingly reported, although their origin remains uncertain. They may be previously unrecognized natural parasites of man or zoonotic infections from other animals.[39] Serological evidence suggests that latent infections may be quite common in man.[39] In a study to investigate the presence of antibodies to *Nosema cuniculi* in human and animal sera, normal blood donors in Singapore did not have detectable antibody titers, but 6 out of 69 apparently normal Caucasians had a low titer of antibodies.[237] High titers of antibodies were also detected in laboratory rabbits, and significant titers in 38 out of 40 sheep.

Encephalitozoon cuniculi is widespread in rodents, rabbits, carnivores, and nonhuman primates as well as occurring commonly in man.[39] Microsporidia belonging to the genera *Nosema, Glugea, Pleistophora, Haplosporidia, Dermocystidium*, and *Sporozoon* commonly infect lower vertebrates (fish, amphibians) and have occasionally been reported in reptiles.[212] There are numerous species in fish, some of which are responsible for mortality or pathological abnormalities sufficient to make affected fish unmarketable.[38]

Epidemiology and Transmission. The widespread occurrence of intestinal microsporidial infection in patients with HIV and the potential for human-to-human fecal-oral transmission[232] suggest that microsporidia may be common enteric human pathogens worldwide, and their frequency may be related to the adequacy of sanitation in the environment. In general, infections appear to be more common in developing countries, but expanding poverty, urban migration, air travel, and immigrant populations in conjunction with other social and environmental changes may explain some of the increase in more developed countries.

The main methods of infection in man largely are unknown, but contaminated water has been suspected.[272] Human-to-human transmission has been postulated to occur via the fecal-oral route, urinary-oral route, eye infection, sexual transmission, or transplacentally.[163]

Only a few species of microsporidia have been recorded from mammals, although one, *Encephalitozoon cuniculi*, has a wide geographic distribution and is transmitted orally and transplacentally.[38] Other microsporidia in mammals may simply be opportunistic parasites causing illness under conditions of immunoincompetence. The presence of large numbers of species of microsporidia in fish and amphibians suggests that the aqueous environment may be a significant factor in their transmission.

Clinical Signs. The clinical conditions caused by microsporidia vary widely; some cause gastrointestinal disturbance, others cause systemic disease, ne-

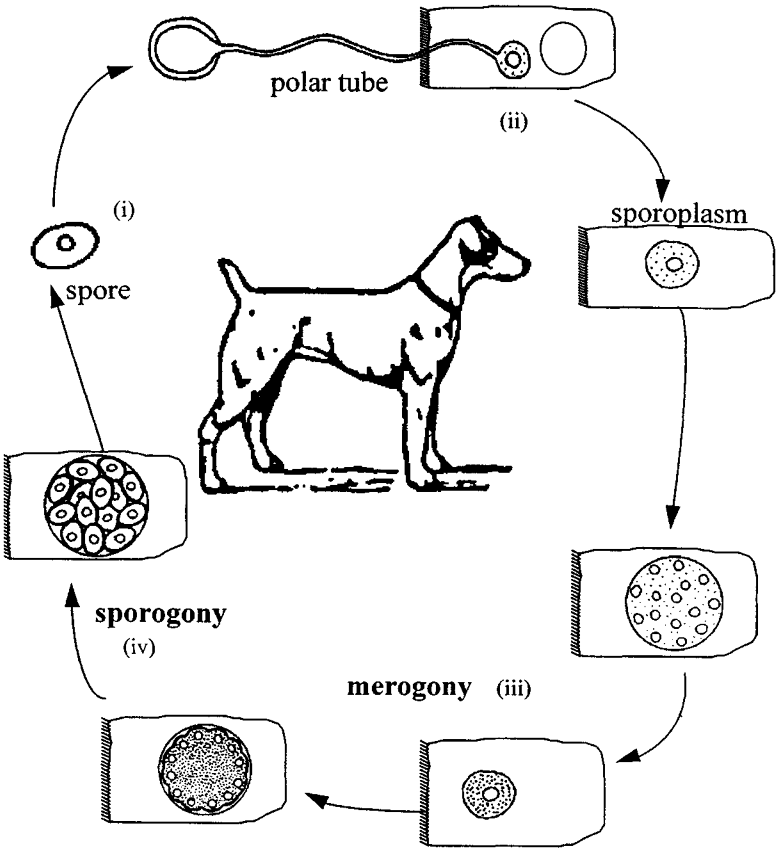

Figure 51–9 Life Cycle of Microsporidia (*Encephalitozoon cuniculi*). Ingestion of a spore (i) by a new host leads to the extrusion of a polar tube, which attaches to a host cell by an anchoring disc (polar sac), and inoculation of the sporoplasm into the cytoplasm of the host cell (ii). There then follows a period of merogony (iii), followed by sporogony (iv), leading to the production of spores.

phritis, and ascites, while others affect the nervous system. Chronic diarrhea, dehydration, and weight loss are the most common signs of microsporidiosis. Most infections are found in HIV patients, with prolonged diarrhea lasting up to 4 years reported and mortality rates of more than 50%.[30,207] Abdominal pain, vomiting, and fever appear to accompany biliary infections. Reported infections in man include keratitis, conjunctivitis, hepatitis, peritonitis, myositis, central nervous system infection, renal disease, and sinusitis.[37,40,176,203,207,227]

E. cuniculi can cause a variety of neurological syndromes in infected mammals. In dogs, transplacental infection of puppies can lead to temperamental changes similar to rabies infection or signs similar to distemper virus leading to fading puppy syndrome. Rabbits also can become infected and often exhibit severe neurological disorders.[39] A plethora of species exist in lower vertebrates, particularly fish, causing a diverse range of clinical and pathological signs affecting the skin, muscle, nervous tissue, intestine, and gonads.[212]

Methods of Detection. The microsporidia are very tiny protozoa between 1 μm and 5 μm in size. Staining techniques include a modified Trichrome staining method,[223] a modification of the standard one-step Trichrome stain using a 10-fold concentration of chromotrope 2R[104] and a rapid fluorescence technique using Uvitex 2B.[263] Although acid-fast, they are difficult to detect and identify by light microscopy, and identification is frequently based on electron microscopy. *Encephalitozoan cuniculi* has been cultured in monolayer culture of rabbit choroid

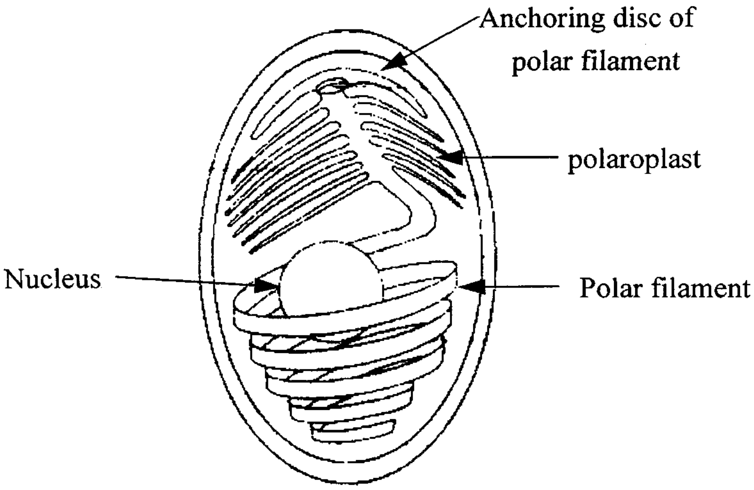

Figure 51–10 Diagrammatic Representation of a Microsporidian Spore Showing the Internal Structures Notably the Extrusion Apparatus Comprising the Coiled Polar Tube and Anchoring Disc. When spores are ingested by a new host, the polar tube is everted. When fully extended, and if the tip of the tube penetrates a host cell, the sporoplasm (nucleus and cytoplasm) passes through the tube and is inoculated into the cytoplasm of the host cell.

plexus cells and numerous cell lines will support its growth. Madin Derby Canine Kidney (MDCK) cells are particularly successful.[41] A method capable of detecting culture-derived *E. cuniculi,* and *E. hellem* and two other human microsporidia, *Enterocytozoon bienusi* and *Septata intestinalis* in formalin-fixed fecal and urine samples, respectively, has been described.[4] An ELISA for detection of antibodies to *E. cuniculi* uses antigen produced from spores derived from tissue culture.[39]

Prevention and Control. Infection is seen predominantly in immunocompromised individuals, and recommendations made for other opportunistic protozoan infections should be followed.

Conclusion. Microsporidia increasingly are being recognized as important human intestinal pathogens mainly in patients infected with HIV but many questions relating to the epidemiology, routes of transmission, and diagnosis remain unanswered. Although many aquatic animals are hosts to microsporidian species, it is not known whether the microsporidia that produce disease in humans have reservoir animal hosts. Microsporidia can survive in water for relatively long periods of time as resistant spores, and because they are much smaller than the resistant stages of other protozoan parasites, they are much more likely to pass through filters used in water treatment processes and to contaminate drinking water.

52 Foodborne Viruses

E. Owen Caul

52.1 Introduction
52.2 Taxonomy of foodborne viruses
52.3 Viral gastroenteritis
  52.3.1 Clinical aspects of viral gastroenteritis
  52.3.2 Pathogenesis of viral gastroenteritis
  52.3.3 Epidemiology of viral gastroenteritis
52.4 Viral hepatitis
  52.4.1 Clinical aspects of hepatitis
52.5 Biophysical properties and virus inactivation

52.1 INTRODUCTION

Human fecal viruses are significant causes of foodborne illness, although it is not possible, at present, to quantify the extent of the problem on a global scale. This is largely due to the lack of comprehensive surveillance systems allied to laboratory diagnosis in most parts of the world. It is, however, clear that enteric viruses commonly are recognized as a cause of human disease associated with foodborne transmission and are almost certainly under-ascertained on a worldwide basis. The diseases caused by foodborne human enteric viruses fall into two major distinct clinical entities that present as viral gastroenteritis or viral hepatitis. Foodborne viral gastroenteritis increasingly is recognized and appears to be a significant public health hazard while foodborne viral hepatitis is less common, at least in the developed world. To understand the mechanisms involved in foodborne transmission, it is fundamental to consider the natural history of these two distinct clinical syndromes, which underpins why foodborne outbreaks occur and has lessons for prevention and management.

As a result of the extensive published epidemiological and laboratory investigations of outbreaks of nonbacterial gastroenteritis, it is apparent that the small round structured viruses (SRSVs) or Norwalk/Norwalk-like viruses commonly are implicated in foodborne gastroenteritis worldwide. In the United Kingdom (UK), SRSVs represent the most significant viral problem to the food industry. While astroviruses and caliciviruses represent a minority of foodborne outbreaks, all three will now be considered. Other enteric diarrhea viruses (eg, Adenovirus types 40/41) have either not been implicated in foodborne gastroenteritis or are exceptionally rare (eg, rotavirus). It is noteworthy that while Group A rotaviruses are recognized as the most common and important cause of childhood diarrhea worldwide, they rarely have been incriminated in foodborne viral gastroenteritis. Epidemiological studies have demonstrated that young children (< 2 yrs old) are particularly susceptible to severe gastroenteritis and that transmission occurs by the fecal/oral route from child to child. Clinically recognizable Group A rotavirus infections in adults are relatively uncommon, probably as a result of immunity derived from infection in childhood and a decreased host susceptibility. Immunity wanes in the elderly and they become susceptible to symptomatic infection with this virus. While Group A rotavirus can survive on fresh fruit and vegetables, transmission to man rarely has been documented. The burden of illness in young children is so large that foodborne transmission, if it occurs, would not be easily recognized. In contrast, Group B rotaviruses have been well recognized as a cause of severe gastroenteritis in adults in China where transmission through drinking water was established. This is unique to China and has not been documented in the UK, Europe, the United States (US), or elsewhere in the world. In view of the paucity of incidents incriminating rotaviruses in foodborne transmission, this virus will not be considered further.

Finally, outbreaks of foodborne viral hepatitis caused by Hepatitis A also are recognized and these will additionally be considered. A résumé of viral gastroenteritis, clinical aspects, pathogenesis, and epidemiology will now be considered followed by Hepatitis A. The laboratory diagnosis of these infections will follow as a separate section and the chapter will conclude with aspects of prevention and control.

52.2 TAXONOMY OF FOODBORNE VIRUSES

The recent molecular characterization of three strains of SRSV has clarified the taxonomic status of this group of viruses.[50,68,113,139] Thus the overall genome organization of SRSVs is compatible with their classification within the Caliciviridiae family[141] and is compatible with early studies on the protein and nucleic acid composition of Norwalk virus.[90,167] SRSVs can be divided into two distinct genetic groups (genotypes I and II) based on the degree of homology recognized within the RNA polymerase or capsid region of the viral genome.[85,86,87,148,225] Importantly, molecular studies also have demonstrated fundamental differences in the genome organization of SRSVs and the classical human enteric caliciviruses.[35,50,140,152,166] Thus SRSVs and the classical human enteric caliciviruses represent two distinct subgroups within the Caliciviridiae family,[50] despite one report suggesting similarities between SRSVs and classical human caliciviruses.[60]

The complete genome organization of astroviruses also has been described recently[228] and these have been allocated to a new family, the Astroviridiae.[171] Hepatitis A has been established as a unique member of the Picornaviridiae and has been classified as a new genus, Hepatovirus.[106] Hepatitis E only recently has been characterized at the molecular level[214] and has been tentatively classified within the family Caliciviridiae. The taxonomic status of all these viruses with their diseases in man is shown in Table 52–1.

52.3 VIRAL GASTROENTERITIS

Diarrheal disease in man, microbiologically distinct from bacterial gastroenteritis, was initially reported more than 50 years ago in the southern US. This clinical syndrome was originally described by Zahorsky[232] as hyperemesis hiemis or winter vomiting disease that reflected both its clinical presentation and distinct seasonality. The illness was documented initially in families where a high secondary attack rate occurred, suggesting a high infectivity. Patients presented with an acute, short, self-limiting episode of vomiting with diarrhea as the main presenting feature. Subsequently, this clinical presentation also was recognized by clinicians in Britain,[27,82] and further laboratory studies established that it was distinguishable from bacterial gastroenteritis. This became particularly clear as a result of investigations of institutional outbreaks where stool cultures were consistently shown to be negative for pathogenic bacteria using the traditional bacteriological techniques available at that time.

Following Zahorsky's original description, other clinicians used their own synonyms to describe the illnesses they investigated; as a result, the literature abounds with a variety of terms. Thus, nonbacterial gastroenteritis, epidemic nonbacterial gastroenteritis, epidemic gastroenteritis, acute infectious nonbacterial gastroenteritis, acute nonbacterial gastroenteritis, and epidemic vomiting disease are examples of the synonyms used between the 1940s and early 1970s to describe this gastrointestinal syndrome. Subsequent studies, using the oral inoculation of human volunteers with a fecal filtrate from symptomatic patients, demonstrated that a transmissible agent was present in human stools.[1,51,70,80,114,198,211] This approach established the potential for a viral cause for these illnesses, and details documenting incubation periods and symptoms produced in volunteers were recorded. Laboratory studies directed toward the isolation of a bacterial pathogen or a viral agent failed, although the natural history of the transmissible agent was comprehensively described.

Table 52–1 Diseases and Taxonomic Status of Foodborne Viruses

Virus	*Disease*	*Family*	*Nucleic Acid*	*Genotypes*	*Serotypes*
SRSV	Epidemic gastroenteritis (all age groups)	Caliciviridae	Single stranded RNA	2	Multiple
Classical Calicivirus	Mainly pediatric gastroenteritis	Caliciviridae	Single stranded RNA	2 (distinct from SRSV)	4
Astrovirus	Mainly pediatric gastroenteritis	Astroviridae	Single stranded RNA	1	7
Hepatitis A	Hepatitis	Hepatovirus	Single stranded RNA	1	1
Hepatitis E	Hepatitis	? Caliciviridae	Single stranded RNA	?	1 serotype currently recognized

Many years elapsed before an investigation of a school outbreak of epidemic gastroenteritis in Norwalk, Ohio, described for the first time a viral etiology for epidemic nonbacterial gastroenteritis.[119] American workers prepared fecal filtrates from stool samples collected from symptomatic patients in this outbreak, which they used to infect human volunteers. They then applied the technique of immune electron microscopy to the examination of stool samples from the volunteers. These studies identified a previously undescribed 27 nm virus-like particle and the Americans coined the term Norwalk virus for this agent in recognition of the geographical setting in which the outbreak occurred. Further detailed studies in human volunteers established the Norwalk virus as the etiological agent responsible for the original outbreak in the primary school.[115] Subsequent laboratory investigations demonstrated either seroconversions or rising IgG titres in serum samples from symptomatic volunteers as well as virus excretion in stool samples. These pioneering human volunteer studies largely fulfilled Koch's postulates and subsequent studies addressed the pathogenesis and clinical features of this new virus. The American workers carried out further volunteer studies using the Norwalk agent and jejunal biopsies were collected from infected volunteers with acute disease. Histopathological studies on these jejunal biopsies provided new insights into the cell tropism of Norwalk virus in the small intestine,[2,206] and all of these studies represented a milestone in expanding our knowledge of human viral gastroenteritis. Further electron microscopical studies on human stools by American workers identified morphologically similar viruses to the Norwalk virus in two separate outbreaks of nonbacterial gastroenteritis. These viruses were called Montgomery County and Hawaii virus respectively,[115] reflecting the geographical setting of the affected patients. The practice of naming small round viruses identified in different outbreaks according to their geographical setting became common[30] and has been continued to the present day. These electron microscopical studies on Norwalk virus heralded the discovery of a variety of morphologically distinct viruses in human stool samples.

The application of electron microscopy to the examination of diarrheic human stool samples became a common investigation worldwide and subsequently resulted in major advances in our understanding of the etiology of nonbacterial gastroenteritis. Rotaviruses were rapidly identified as major pathogens in endemic infantile gastroenteritis, and other taxonomically distinct viruses, including fastidious adenoviruses, were added to the increasing list of newly described enteric diarrhea viruses.[48] Numerous reports subsequently demonstrated an apparently wide range of small round viruses that varied in size and surface morphology. In many studies, small round viruses were identified by immune electron microscopy (IEM) as a result of aggregation following the use of human sera. The addition of human antibody to fecal viruses masks the surface morphology of virus particles, and this resulted in a confusing picture of the etiology of nonbacterial gastroenteritis.[30] In other reports, small round viruses were identified from their classical surface morphology in the electron microscope after negative staining and detailed descriptions of the surface morphology of astroviruses and classical caliciviruses were published for the first time.[160–162]

In an attempt to bring some order to the standardized recognition and reporting of the many small round viruses being described in the literature, an interim classification scheme was published.[36] This scheme was adopted to aid national surveillance within the UK and to establish which of the small round viruses were related causally to viral gastroenteritis. The study defined comparative morphological criteria derived from examining taxonomically established human and animal small round viruses. The authors concluded that small round human enteric viruses could be readily subdivided into those viruses that lacked a resolvable surface structure and that could be described as featureless viruses and those that had an obvious resolvable surface structure in the electron microscope. The first group (featureless viruses) included both picornaviruses (which do not cause gastroenteritis) and parvovirus-like particles that were represented by the Wollan, Ditchling, Cockle, and the Australian Paramatta[49] agents. All four agents (parvovirus-like) previously had been implicated in outbreaks of nonbacterial gastroenteritis but conclusive evidence of their role in human disease never has been proven and this remains the situation to date.[5,7,30]

The second group of small round viruses all possessed a resolvable surface morphology in the electron microscope that often was descriptive and included the previously described and taxonomically distinct astroviruses, and "classical" caliciviruses. Other viruses morphologically distinct from both astroviruses and classical caliciviruses shared a common surface structure and were described as virus particles with an amorphous surface structure lacking geometric symmetry and possessing a ragged outline.[36] This latter group of viruses was represented by the prototype Norwalk virus and subsequently Hawaii, Montgomery County, and many other morphologically indistinguishable viruses were included. This latter subgroup of viruses, which were distinguishable morphologically from both astroviruses and the classical caliciviruses, were called collectively SRSV or Norwalk-like viruses. A prerequisite of this study was that all viruses were examined without the addition of human antibody to ensure that any surface structure would not be obscured. A modification of this interim classification scheme is shown in Figure 52–1 and provides examples of those currently recognized viruses that are classified as SRSVs. This interim classification scheme has proved reliable and reproducible in accurately identifying SRSVs and recently has been adopted by other workers.[115]

An important aspect of this classification scheme was that it recognized fundamental morphological differences between SRSVs and the classical caliciviruses. These observations also were supported by both epidemiological and immunological distinctions[18,30] discussed later. Recent advances in the molecular characterization of SRSVs and the classical caliciviruses also have demonstrated significant differences at the molecular level[139,140] despite the recent classification of SRSVs within the family Caliciviridiae.[68,113,139] Thus, the initial distinctions made at the epidemiological, immunobiological, and electron microscopical level have been confirmed at the molecular level. These results suggest that SRSVs are a distinct subgroup within the Caliciviridiae family and are distinguishable from the classical human caliciviruses; thus SRSVs and the classical caliciviruses will be considered separately, which emphasizes their different epidemiological roles in human disease and recognizes their distinction at the molecular level.

52.3.1 Clinical Aspects of Viral Gastroenteritis

SRSV. Detailed information on the clinical manifestations of SRSVs has been established from both epidemiological as well as comprehensive volunteer studies.[115,116,118] Illness in naturally acquired infections, as well as those induced in volunteers, produced by Norwalk virus, Hawaii agent, the Montgomery County agent, and the Snow Mountain agent and other SRSVs, is clinically indistinguishable.[73,115,231] Volunteer studies and epidemiological studies have documented a mean incubation period of approximately 24 hours[30,115] with a dose-dependent range of 15 to 50 hours.[33,34] Symptoms are sudden in onset without a defined program and often are accompanied by nausea and vomiting, which can be projectile and severe. A low-grade fever and diarrhea are common presentations, with the latter being relatively mild to moderate in severity. A significant observation, in contrast to bacterial gastroenteritis, was that diarrheal stools did not contain blood, mucus, or white cells. Other symptoms included mild abdominal pain or cramps, malaise, and headaches. Vomiting may arise from a decrease in gastric mobility giving rise to a reflux action into the stomach.[30,34,115,116] Respiratory symptoms have not been documented and volunteer studies, using nasopharyngeal washings from an acutely ill volunteer, did not induce disease on passage to other volunteers.[70]

In general, SRSV infections are mild and self-limited, and affected patients rarely require hospitaliza-

tion, but cases are highly infectious. Occasional reports have, however, documented severe dehydration in some elderly patients, which required correction through the administration of intravenous fluids. Deaths arising from SRSV infections are unusual and have not been directly attributed to this group of viruses.[121]

Calicivirus. Symptomatic calicivirus infection occurs most commonly in infants and young children where it has been considered indistinguishable from the milder forms of rotavirus infection[55–57,61–65,213] Following transmission, there is an incubation period of 1 to 3 days, with symptoms persisting for an average of 4 days. Diarrhea and vomiting are common, whereas a fever with upper respiratory symptoms is less pronounced. There is no evidence that caliciviruses replicate in respiratory mucosal cells or that respiratory spread occurs. Because respiratory symptoms have been described mainly in young children, it is possible that they arise from concomitant respiratory viral infections, which are common in young children. Limited adult volunteer studies have been carried out where the virus was administered by the nasal/oral route.[55] Symptoms ranged from inapparent or mild to moderately severe and the latter included nausea, vomiting, diarrhea, pyrexia, and abdominal pain. The clinical presentations observed in these volunteer studies are compatible with those seen in naturally acquired infections.

Astrovirus. Astrovirus infection in man is followed by an incubation period of 3 to 4 days before the patient presents with symptoms of gastroenteritis. Affected patients present with systemic signs and symptoms including a fever (37° C), diarrhea, headache, nausea, malaise, and, uncommonly, vomiting.[135] Adult infections tend to be more severe than pediatric infections. These clinical features are similar to other viruses that cause gastroenteritis and are not clinically diagnostic.

52.3.2 Pathogenesis of Viral Gastroenteritis

SRSV. Virus replication is considered to occur within the mucosal epithelium of the small intestine despite the fact that direct evidence of such events has not been demonstrated. Ultrastructural studies, by light and electron microscopy, of jejunal biopsies from volunteers infected with Norwalk virus showed a partial flattening and broadening of the intestinal villi with disorganization of the mucosal epithelium.[2,206] The lamina propria was infiltrated with mononuclear cells and vacuolation of mucosal epithelium was noted. A crypt cell hyperplasia was a common finding, presumably in response to villous epithelium damage. Mucosal epithelial cells showed dilatation of the rough and smooth endoplasmic reticulum with an increase in multivesiculate bodies. Microvilli markedly were shortened and amorphous electron-dense material was present in the expanded intercellular spaces. Of considerable interest in these studies was the absence of recognizable virus particles in damaged mucosal cells. Similar results at the light microscopy and ultrastructural level also have been described from studies of volunteers infected with the Hawaii agent.[72,207] Overall, SRSV infections appear to cause a mild villous atrophy arising from limited virus replication in mucosal epithelium. These histopathological studies also demonstrated that the appearance of mucosal lesions in the small intestine was paralleled by a decrease in brush border enzymes that returned to normal levels in convalescence.[2]

Calicivirus. Unlike astroviruses, SRSVs, and other enteric viral pathogens, comprehensive ultrastructural studies of human caliciviruses in the gut have not been reported. Early studies in the UK demonstrated caliciviruses, by negative-staining electron microscopy, in the small intestinal gut lumen of a child who had died from gastroenteritis.[76] They were, however, unable to establish an etiological role because there were other complicating factors, and ultrastructural studies were not performed. An analogy with all the other diarrheal viruses would lead to the assumption that caliciviruses replicate in mucosal cells lining the villi of the small intestine. Extensive studies on the pathology of a bovine calicivirus-like agent (Newbury agent) have been carried out that demonstrated damage to enterocytes at the villus base.[94] The relevance of these studies to the pathogenesis of the classical human caliciviruses is unclear.

Astrovirus. Limited studies in man have shown that astroviruses infect the mucosal epithelium of the lower parts of the villi in the duodenum.[191] Crystalline arrays of astrovirus particles within the cytoplasm have been noted. The limited ultrastructural studies of astrovirus infections in man that have been reported are compatible with those observed in the small intestine of lambs that documented a transient villous atrophy.[209] In one study of human astrovirus infections, a short-term monosaccharide intolerance was reported[180] but this is not a serious sequel.

Virus replication within mucosal epithelial cells presumably results in cell lysis and release of astrovirus particles into the gut lumen where they become detectable in fecal samples. Virus excretion can be followed by diarrhea that is sometimes watery, although asymptomatic excretion is common. Diarrhea usually lasts for 2 to 3 days but may continue for a week or longer, and virus excretion persists while symptoms last. During the acute stage of the disease, 10^{10} particles per gram of feces can be detected in stool samples. Persistent symptomatic excretion has been documented for months in immunocompromised patients,[137] and such cases may be an important source for nosocomial infections.

Human volunteer studies have been carried out in an attempt to demonstrate that astroviruses are enteric pathogens. In these UK studies, 17 volunteers were infected with a fecal filtrate containing astroviruses and, subsequently, one volunteer developed diarrhea and a further four asymptomatic volunteers excreted astroviruses. These studies suggested that volunteers with pre-existing antibody prior to challenge were protected from symptomatic re-infection.[135,137] Although these adult volunteer studies are useful in assessing the potential of astroviruses as enteric pathogens and provide important clinical information, they are limited in assessing the overall burden of symptomatic primary infections in children, where the majority of infections occur.

52.3.3 Epidemiology of Viral Gastroenteritis (All Sources)

SRSV. SRSVs are now established as the most important cause of epidemic nonbacterial outbreaks of gastroenteritis throughout the world.[18,19,30,32,34,35,38,69,91,115,116,118,120,121,223] Extensive sero-epidemiological studies in the US, and the direct detection of SRSVs by electron microscopy particularly in the UK and Japan as well as elsewhere in the world, have reinforced the importance of these viruses in communitywide outbreaks, which often have significant economic importance. National initiatives directed toward the surveillance, ascertainment, and diagnosis by electron microscopy of UK outbreaks of nonbacterial gastroenteritis have recently shown that SRSVs are now a more common cause of outbreaks than salmonella and have provided important epidemiological data for many years. These data demonstrate an increasing prevalence of SRSVs in recent years with the suggestion of a winter seasonality (Figure 52–2) and show that all age groups are affected (Figure 52–3). This is epidemiologically different from that documented for caliciviruses and astroviruses, which demonstrates that these latter viruses are predominantly pediatric infections (see Figures 52–4 and 52–7).

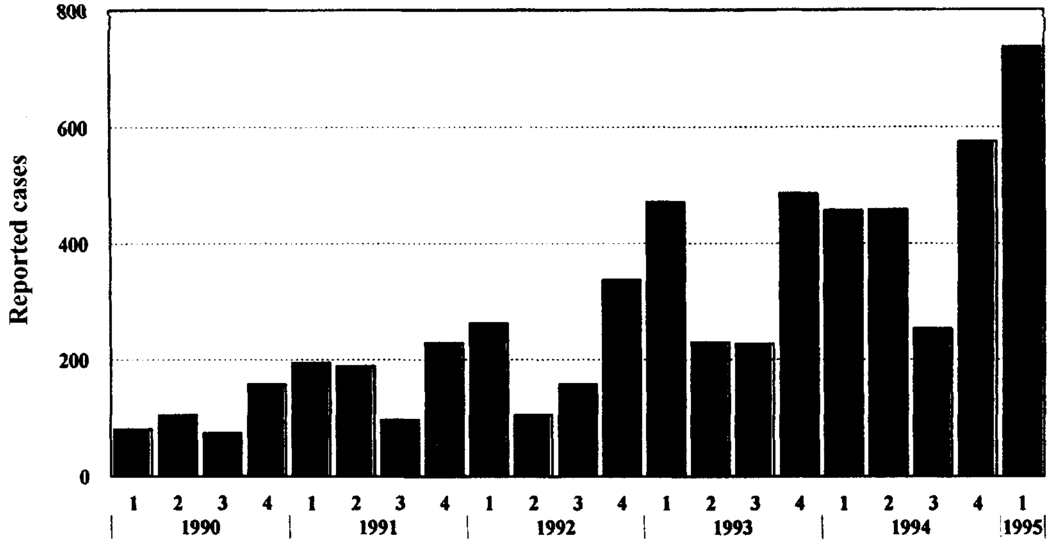

Figure 52–2 Total Numbers of SRSV in England and Wales by Quarter. Laboratory reports to Public Health Laboratory Service, Communicable Disease Surveillance Centre (CDSC) 1990–1995.

The diversity of settings associated with these economically important SRSVs is demonstrated by the early work in the US. The Norwalk virus caused a communitywide outbreak in Ohio, and the Hawaii and Montgomery County agents were responsible for small family outbreaks.[30,69,115,116,118] In contrast, the Snow Mountain agent caused an epidemic at a holiday camp in Colorado.[172] On the other side of the Atlantic, the Taunton agent was shown to cause considerable disruption in an orthopaedic and geriatric ward in southern England.[30,190] Subsequent surveillance and investigations of outbreaks in many parts of the world have identified the potential that SRSVs have for causing epidemic gastroenteritis in semiclosed or communitywide populations associated with families,[115,118] health care, holiday, and travel including cruise ships, schools, or higher education and the catering industry.[30,35,38,48,65,69,91,105,121,201,211] Epidemiological studies also have shown that outbreaks commonly occur in children and in adults, particularly the elderly, but less commonly in neonates or very young children.[18,30,35] These observations contrast with those of the classical caliciviruses that are rarely associated with epidemic gastroenteritis in adults. Although considerable data are available on the causal role of SRSVs in outbreaks, less is known about their endemic role in disease, which might be attributed to the short-lived and relative mildness of the presenting clinical features. As a result, hospitalization of individual cases is unusual and the opportunity to investigate sporadic cases is not usually possible.

Sero-Prevalence. The inability to propagate SRSVs in cell culture and the lack of a suitable animal model have severely limited sero-prevalence studies. American workers developed a number of serological assays, using fecal extracts containing Norwalk virus, to assess the acquisition of Norwalk antibody in populations in different countries.[91,115,117] Their studies showed that the presence of Norwalk antibody was acquired gradually during childhood with approximately 20% of children under 5 years old being positive. The prevalence of antibody in adolescence through early adulthood rose rapidly to 45% in 18- to 35-year-olds and 55% to 60% in 45- to 65-year-olds. This epidemiological picture is compatible with the natural history of SRSVs, which mainly cause outbreaks in older children and adults, and contrasts with that reported for astroviruses, caliciviruses, and rotaviruses. In contrast to the sero-prevalence documented in developed countries, acquisition of antibody to Norwalk virus in underdeveloped countries occurs at a very young age. Studies in Bangladesh and Ecuador showed that 75% to 100% of children had acquired antibody, while in Yugoslavia the sero-prevalence rate was intermediate between the US and less-developed countries.[115] Similar results have been re-

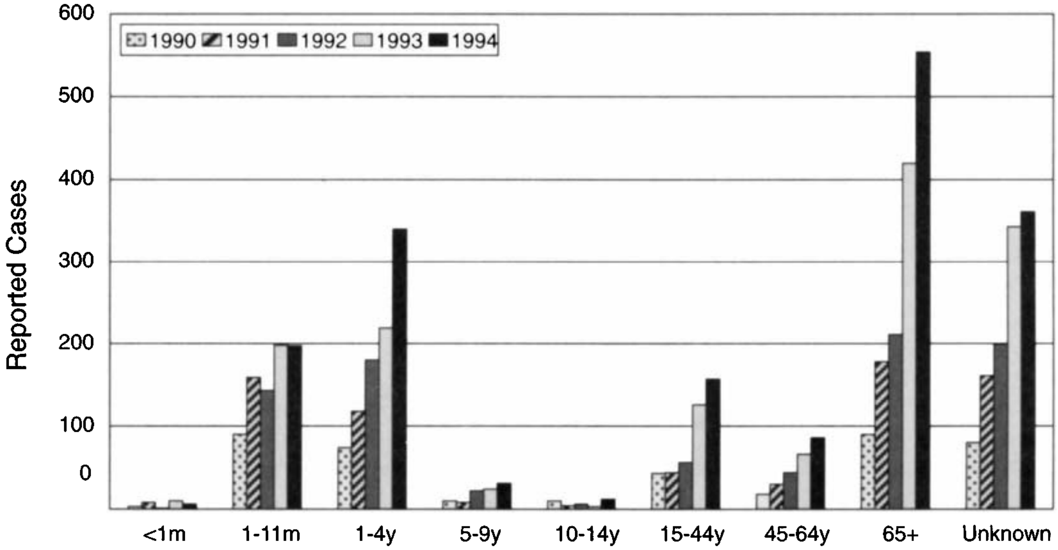

Figure 52–3 Total Numbers of SRSV by Age Group. Laboratory reports to CDSC for England and Wales 1990–1994.

ported from Taiwan and the Philippines. Reports of Norwalk virus antibody in blood donors from the US, Belgium, Yugoslavia, and Switzerland range from 54% to 77% and emphasize the ubiquitous nature of Norwalk virus in the world. Compelling evidence that Norwalk virus was responsible for many outbreaks throughout the world in the 1970s has been demonstrated by serological responses measured by a radioimmune assay (RIA).[115] All of these studies were carried out when Norwalk virus was circulating in the community. Current evidence, at the molecular level, suggests that Norwalk virus is no longer circulating in the US or in the UK and further sero-epidemiological studies using currently circulating SRSV strains as a source of antigen are now indicated.

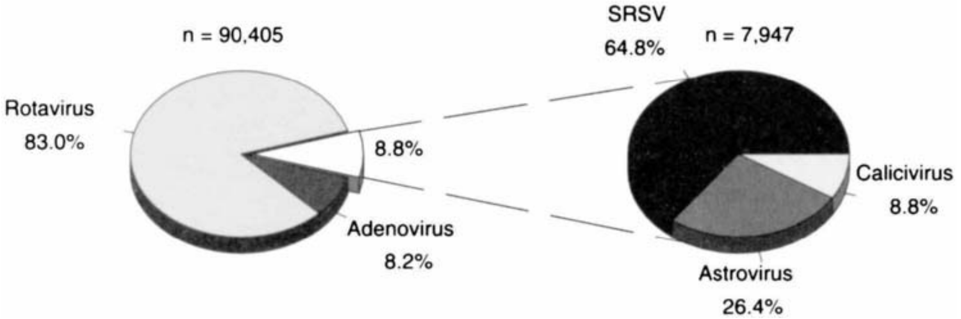

Figure 52–5 Enteric Viruses in England and Wales. Total number of laboratory reports from all sources to CDSC 1990–1994 denoting percentages attributable to rotaviruses, adenoviruses, and small round viruses.

The recent expression of Norwalk virus capsids in Baculovirus vectors is a major advance and has allowed further serological studies to be carried out on historical human serum using defined reagents in an enzyme-immunoassay (EIA) format.[218] Early results in the UK using these newly developed reagents suggest that approximately 25% of children aged 6 to 11 months old had Norwalk antibody and this increased to 90% in individuals over 60 years of age.[83] The high level of antibody to Norwalk virus documented in this report contrasts with the molecular epidemiology of SRSVs that has not identified Norwalk virus as a circulating strain in recent years. The possibility that these assays are detecting heterologous SRSV responses rather than specific Norwalk virus antibody should be considered.

Calicivirus. In common with the other diarrheal viruses, most of our data on the epidemiology of caliciviruses are derived from the detection of the virus by electron microscopy and limited sero-prevalence studies.

The first reports of a human enteric calicivirus came from studies carried out in Glasgow.[159-162] These workers were investigating the causes of gastroenteritis in children and detected classical calicivirus particles in both symptomatic and asymptomatic children. These studies failed to assign a causal role for caliciviruses in human disease because 20% of children excreting caliciviruses were asymptomatic. Subsequently, an outbreak of gastroenteritis in an infant and junior school in North London was investigated and caliciviruses were conclusively shown to be the causal agent.[61,63] This outbreak was described as winter vomiting disease, although spread to children in other classes in the school and to home contacts was negligible. The authors also postulated that spread to other children was limited because they were probably immune. These epidemiological and immunological features are not consistent with classical winter vomiting disease, which is now recognized as being caused by SRSVs. Since these early studies, evidence on a continual scale has incriminated caliciviruses in human enteric gastroenteritis and they are now established as enteric pathogens.[30,34,48,57,64,89,93,102,125] Numerous studies and surveys of sporadic cases of gastroenteritis in children have documented excretion rates from 0.9% to 6.6% in hospitalized children around the world.[35,57,61,125,159,163,169,213] A similar excretion rate (2.9%) has been reported in a US study in a daycare center.[165] All of these studies documenting calicivirus infection in hospitalized children suggest that, as astroviruses, they are a minor cause of clinically significant disease. Neonatal infection is often subclinical in contrast to that seen in older children and nosocomial spread has been described. The clinical importance of human enteric caliciviruses in the UK has been addressed and analyzed from national data reported by electron microscopy units. During the course of surveillance between 1985 and 1987, caliciviruses accounted for 0.9% of the total number of positive identifications from all sources of diarrheal viruses reported.[170] Over 90% of positive calicivirus identifications (1990–1994) were documented in children under 5 years of age (Figure 52–4).

Analysis of more recent national data (1990–1994) in England and Wales shows that caliciviruses accounted for 0.8% of all positive diarrhea virus reports from all sources, which is remarkably consistent with the previous studies. Further analysis of data, taking into account only small round viruses associated with diarrhea during this study period, showed that caliciviruses account for 8.8% of all small round viruses reported (Figure 52–5). The conclusions drawn from these national studies are that caliciviruses are a minor cause of clinically significant disease in the UK and suggest that infected children are uncommonly admitted to hospital.

Human calicivirus infections usually occur as sporadic cases in young children, but community and nosocomial outbreaks have also been recognized. Outbreaks have been documented in America,[165] Japan,[47,181] Australia,[93] and England,[57,61-64,109,138] and were documented not only in children,[30,35,47,48,57,62,89,93,109,165,181,213] but also among elderly patients in nursing homes[64,84,89] where the attack rate in some outbreaks ranged from 50% to 70%. Outbreaks in adults and elderly patients appear to be unusual and may represent infection in the face of a waning immunity. A distinct seasonality has not been described for calicivirus infections and it is apparent from the British studies that this virus is endemic in the community (Figure 52–6).

Sero-Prevalence. Studies in Japan have demonstrated that antibody to calicivirus is rapidly acquired between 6 months and 2 years of age with a sero-prevalence of 30%. This rises to 65% in 2- to 5-year-olds. In older children and adults, approximately 90% have acquired specific antibody.[178,203] Similar results have been documented in sero-prevalence studies in the US.[179] Confirmation of this high seroprevalence using pooled gamma-globulin and serum samples has been reported from all continents.[48,57] The high sero-prevalence in early childhood is in agreement with the documented excretion of human caliciviruses in young children. These data also suggest that asymptomatic or at least clinically insignificant disease in childhood is common in view of the paucity of calicivirus reports from hospitalized children with diarrhea. Overall the rapid acquisition of both calicivirus and astrovirus antibodies in childhood is similar to that seen in rotavirus infections and markedly different from that reported for SRSVs.

Astrovirus. Most of our knowledge on the epidemiology of astroviruses is based on the detection of morphologically typical particles by electron microscopy[159,160,162,163] and on limited sero-prevalence studies. The virus has been detected and reported from all five continents,[30,35,135] where a close association with childhood diarrhea has been recorded.[18,30,34,48,65,89,102,135]

Early studies in Glasgow in the 1970s showed that 80% of babies excreting astroviruses were symptomatic, while 12% had no diarrhea.[159,163] Nosocomial spread is well documented, and many outbreaks of astrovirus gastroenteritis in infants and young children have been described in nurseries and pediatric wards.[11,18,30,35,48,65,89,102,128,135,138] In one large pediatric outbreak in Japan, over 50% of children were symptomatic,[128] and, in another outbreak in a children's ward in the UK, spread to nursing staff occurred,[11,138] indicating that susceptibility is not restricted to neonates and children. In nurseries and pediatric wards, astroviruses can become endemic as a result of continually introducing new, susceptible children. Asymptomatic excretion (5% to 20%) has been reported in both neonates and young children; this represents a significant source for further spread of the virus in semiclosed communities.

Within our current knowledge, astroviruses appear to be a relatively minor cause of gastroenteritis in young children and are only occasionally incriminated in adult disease. Detailed longitudinal studies on astrovirus infections in the community have only rarely been reported. Analysis of surveillance data in England and Wales over a 3-year period between 1985 and 1987, based on electron microscopical observations, showed that astroviruses are endemic within the community with distinct peaks in the winter.[170] This seasonality appears to be constant in temperate climates. In the UK studies, a striking age-related prevalence was noted where the majority of reported symptomatic infections occurred in children under the age of 5 (Figure 52–7).

In a separate longitudinal study of infantile gastroenteritis in London, astrovirus infection was reported in 2.8% of children under age 6 (50/1,802), but none in children between the ages of 6 and 12 years.[61] National surveillance data in England and Wales confirm that astroviruses appear to be a minor cause of viral gastroenteritis in the UK and emphasize the seasonal distribution (Figure 52–8).

In contrast, sporadic cases or outbreaks in adults rarely are reported. In one outbreak in a convalescent home for the elderly in Marin County, California, 51% of residents developed gastroenteritis and the outbreak persisted for 3 months.[184] Although the virus was initially reported as a Norwalk-like agent, the published micrographs suggested an astrovirus morphology;[30] this has subsequently been confirmed.[101] An unusually large outbreak of gastroenteritis affecting both students and teachers has been reported by Japanese workers.[182] Sporadic cases in young adults also occur, which give rise to moderately severe diarrhea.

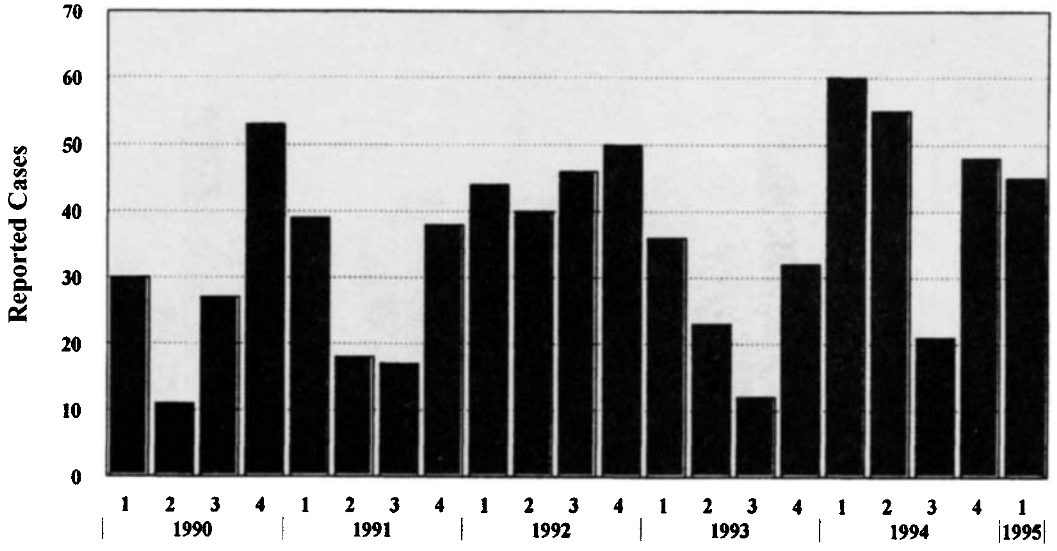

Figure 52–6 Caliciviruses in England and Wales. Laboratory reports to CDSC 1990–1995.

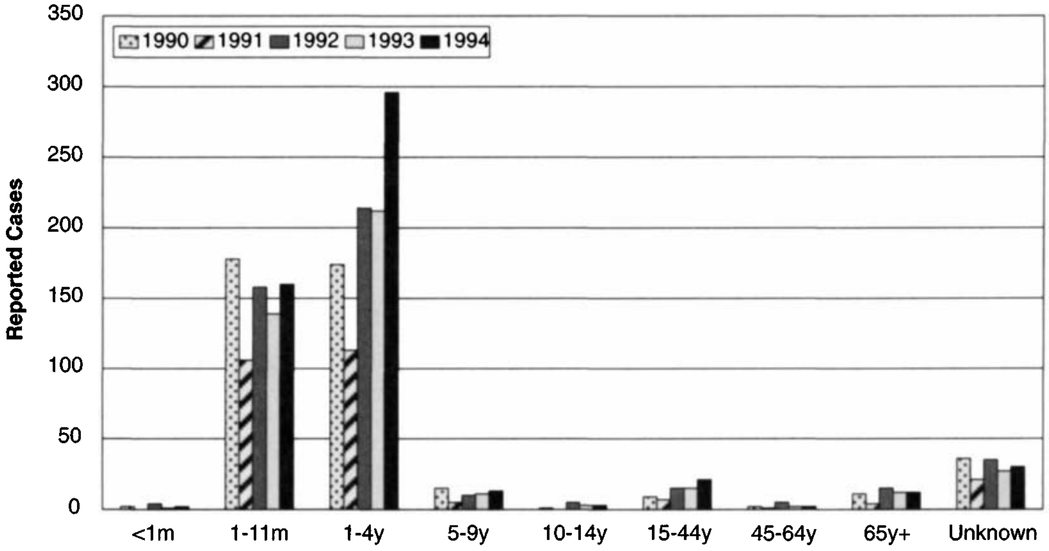

Figure 52–7 Astrovirus by Age Groups. Laboratory reports from all sources to CDSC from England and Wales 1990–1994.

Sero-Prevalence. Limited antibody prevalence studies have reinforced the observations that astroviruses are a minor cause of clinically significant disease in young children. One study in Oxfordshire, England, showed that 64% of 3– to 4-year-olds had been infected; this prevalence rose to 87% in 5- to 10-year-old children.[136] These data are compatible with the epidemiology of astrovirus infections, which demonstrate that the majority of infections occur in young children (Figure 52–7). This high prevalence of antibody in young children and the relatively low percentage of reported

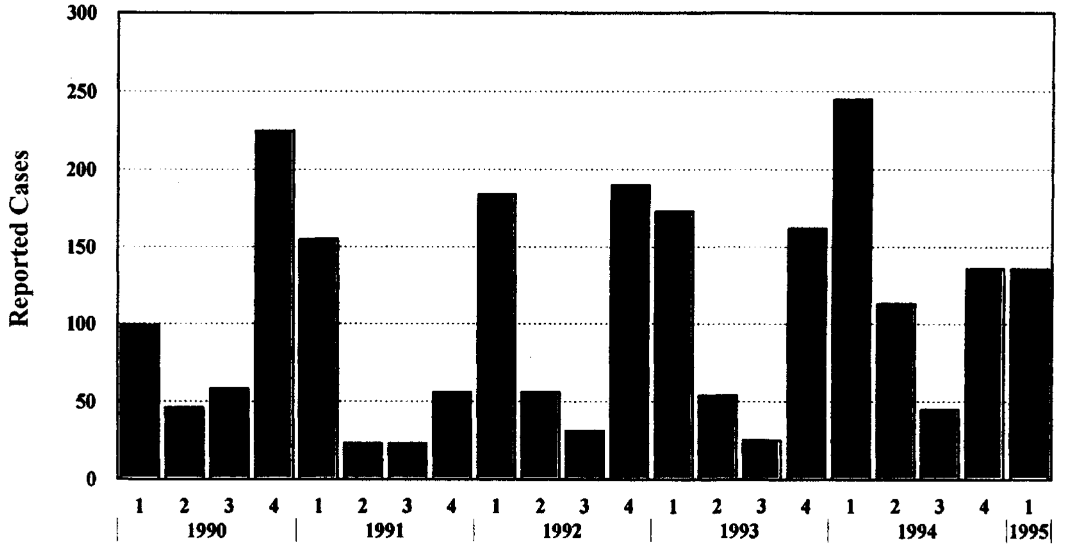

Figure 52–8 Seasonal Distribution of Astrovirus in England and Wales, Laboratory Reports from All Sources to CDSC 1990–1995.

astroviruses from symptomatic cases suggest that many infections are either subclinical or so mild that medical intervention is not required.

Some workers have suggested that the difficulties associated with the definitive identification of astroviruses in human fecal samples by electron microscopy has underestimated their role in viral gastroenteritis and that the recent application of molecular techniques has significantly increased their detection in clinical samples.[229] Other studies have suggested that astroviruses are second in importance to rotaviruses as a cause of viral gastroenteritis in young children.[89,102] These conclusions, however, are not sustainable unless comparable techniques are applied to all other enteric viruses, which in turn are likely to increase their detection.[35]

52.4 VIRAL HEPATITIS

Viral hepatitis in man is caused by at least six taxonomically distinct viruses classified as types A through F.[168,194] Two of these viral agents (A and E) are recognized as enteric infections and are transmitted either by the fecal/oral (Hepatitis A) or waterborne (Hepatitis A and E) route. These routes of transmission have obvious implications for foodborne human disease.

Hepatitis A originally was recognized more than 2,000 years ago when it was described as infectious icterus,[130,131] reflecting the appearance of jaundice in affected patients. Subsequently, the term viral hepatitis type A was proposed by McCallum in the 1940s[157,158] and this was adopted worldwide. The term infective or infectious hepatitis is commonly used in Europe and the US to denote the same syndrome. Extensive worldwide outbreaks of Hepatitis A have been recorded over the last three centuries involving many thousands of people, particularly during the course of World Wars I and II and civil wars.[130,131,168] Human volunteer studies were pivotal to the characterization of the disease and its distinction from Hepatitis B virus.[106] All the early attempts to propagate Hepatitis A in cell culture or in laboratory animal models, including a variety of nonhuman primates, failed and were reported at a symposium in 1954 in the US.[130]

In the 1970s, three important breakthroughs occurred in the study of Hepatitis A infection. Firstly, Hepatitis A virus was visualized for the first time as a result of using immune electron microscopy for the examination of stool samples from infected individuals.[75] These workers described the presence of 27 nm particles that were complexed by the addition of human antibody from patients convalescing from the disease. These studies represented a milestone in the study of Hepatitis A infection in man, and the specificity of this virus as the etiological agent was confirmed by the demonstration of rising antibody titers in affected patients.[75]

The second important breakthrough came with the development of animal models[106] and the description of 27 nm particles in the liver of infected marmosets. Thus by the end of 1974, the agent of viral hepatitis type A had been visualized and an animal model had been described. These studies were fundamental to the expansion of our knowledge on the characterization of Hepatitis A virus[23,193] and its disease and led to the development of a variety of immunological assays used to study the epidemiology of this infection.[26] Finally the difficulties and frustration that many workers had experienced in attempting the in vitro propagation of Hepatitis A in cell cultures were overcome.[192] These studies, demonstrating the growth and passage of Hepatitis A virus in cell culture, were fundamental to its characterization and were the springboard for the development of a safe inactivated human vaccine that is now widely available.

Epidemics of human hepatitis unrelated to either Hepatitis A or B (non A, non B, non C hepatitis) recently have been recognized in Asia, Africa, and Mexico.[15,196] Although the disease initially resembled Hepatitis A, it became clear that this was not the etiological agent as a result of serological tests that excluded both Hepatitis A and B. Thus a new human disease culminating in a hepatitic clinical presentation was recognized that was transmitted by the fecal/oral route.[9,15,16,20] Studies in Soviet Central Asia by IEM identified for the first time a virus etiology for this new form of human hepatitis[16] by aggregating virus particles in human fecal samples with specific antibody; subsequently, the agent has been designated Hepatitis E virus (HEV).[21] Animal models have been important in the study of Hepatitis E infections in man;[24] these have included the use of cynomologous monkeys, owl monkeys, macaques, and tamarins.[25,129] These studies have established that HEV is the etiological agent of non-A non-B hepatitis in man by the demonstration of seroconversions in human cases and in experimentally infected primates.[8,20–22,24,27]

Outbreaks of Hepatitis E in man have only recently been recognized,[15,20–22,24,29,40,234] largely because of the difficulties associated with its specific laboratory identification and the inability to propagate the virus serially in cell culture. Progress is now being made arising from the molecular characterization of the viral genome,[199,214,215] which suggests that it is a member of the Caliciviridiae family. Hepatitis E is currently recognized as an important health problem in Asia, Africa, and Central America[15,21,29,40,222,234] in contrast to its low prevalence in the US and Western Europe. Recent reports have identified Hepatitis E infections among American travelers to Mexico, India, Pakistan, and Nepal.[40]

Although Hepatitis E is currently not a recognized public health problem in the UK, US, or Western Europe,[205] waterborne outbreaks have been described in developing countries.[21,40,216,234] To date, foodborne outbreaks have not been documented. Hepatitis E may therefore become an important food- or waterborne disease in developed countries in the future. Routine laboratory methods are not yet available for Hepatitis E, but future methods will certainly include molecular epidemiological studies and laboratory diagnosis of affected patients by the demonstration of specific IgM responses. Recent studies have demonstrated the application of Hepatitis E baculovirus-expressed capsid proteins in the development of an enzyme-linked immunosorbent assay (ELISA) for the detection of anti-HEV antibodies.[132,153,216,220] This assay will provide a means of establishing the sero-epidemiology of Hepatitis E virus in developed as well as developing countries. Now that the viral genome has been characterized, molecular methods can be developed (polymerase chain reaction [PCR]) to investigate putative water or foodborne outbreaks in the future.

52.4.1 Clinical Aspects of Hepatitis

Hepatitis A. Infection with Hepatitis A virus is followed by an incubation period of 10 to 50 days, which is dose-dependent. The outcome is extremely variable, ranging from asymptomatic or subclinical infection (common in children) to anicteric hepatitis (without jaundice) or icteric hepatitis (jaundice). Symptoms can range from mild to severe and prolonged. Prior to the onset of hepatitis, the patient commonly develops anorexia, fever, malaise, fatigue, myalgia, nausea, and vomiting. Affected patients are infectious prior to the onset of hepatitis and for a few days after the development of jaundice. The excretion of Hepatitis A virus in infected individuals prior to the onset of clinically recognizable disease is an important factor in foodborne transmission.

Pathogenesis. Natural infection with Hepatitis A virus follows ingestion of the virus by the fecal/oral route. The acid stability of the virus allows passage through the stomach and it enters the host via the gastrointestinal tract. From this point of entry, the virus replicates within hepatocytes in its primary site—namely the liver. At the peak of virus replication, there is little liver damage, suggesting that other mechanisms are involved in the pathology of Hepatitis A infection. Although not yet conclusive, it has been suggested that liver damage may result from immune mechanisms after viral replication.[106,195]

Epidemiology. Worldwide, Hepatitis A is one of the most common causes of infectious jaundice, and recurrent epidemics are well recognized.[106,168] Rates of infection are highest in children and young adults in low socioeconomic groups in developing countries. Sanitation, polluted water supplies, and poor personal hygiene are major factors in the spread of the virus; in these settings, where overcrowding also occurs, infection in the young can reach 100%. Person-to-person spread by the fecal/oral route is the major mode of Hepatitis A transmission. There have been more than 35 outbreaks in man where infection occurred from close contact with infected primates (usually chimpanzees). Human cases in these outbreaks have usually involved the animal caretaker.[106]

In contrast, in populations in the developed world that have adequate sanitation, less crowding and facilities for improved hygiene, infection occurs in older age groups. This essentially means that in modern developed societies, large segments of the population remain susceptible. In these situations, large outbreaks can and do occur following the introduction of the virus into a community. As subclinical infection is common in young children, it is worth emphasizing that the first indication of a Hepatitis A outbreak in a community may be symptomatic infection in adults following exposure to their asymptomatic young children. Spread of the virus in young schoolchildren in modern societies often occurs because of a reduction in standards of personal hygiene in the school environment. In the UK, many of the Hepatitis A infections that occur in older children and adults result in several clinically recognized diseases.[103] Three main patterns of disease can be recognized, namely sporadic cases, often in adult travelers returning from countries with a high endemicity,[210] common-source outbreaks (food related), or large community outbreaks that evolve slowly. In the latter case, school-age children and young adults predominate where spread has occurred by the person-to-person route. Between 1987 and 1991, the annual notification rate for Hepatitis A in the UK increased from 3.6 to 14.6 per 100,000 population; however, although the disease occurs throughout the world, incidence figures are unreliable because most cases are either mild or subclinical and are therefore not reported.[168]

Sero-Prevalence. Hepatitis A antibody acquisition is directly related to the standards of sanitation, personal hygiene, and overcrowding. In underdeveloped countries, exposure occurs at a very young age and sero-prevalence may reach more than 90% in the first decade of life. Thus considerable geographical variation in incidence occurs with wide differences in sero-prevalence between different countries.[168] In modern societies with improved sanitation, infection is less frequent, and more than 50% of the population may reach adult life without any evidence of exposure as determined by antibody prevalence studies. Clearly this will be dependent on the socioeconomic groups investigated. Sero-prevalence studies in the UK (1986–1995) have shown that a higher proportion of young children were immune to Hepatitis A in the north of England than in the south,[103] suggesting greater exposure in the north of the country. These sero-epidemiological studies in the UK and also in the US have shown that the incidence of Hepatitis A infection has fallen in the last decade and that there is the considerable potential for future epidemics as the majority of the adult population remain susceptible.[103,168] Food- or waterborne transmission of Hepatitis A to a largely susceptible population in the developed world is an obvious future threat, giving rise to the potential for large communitywide outbreaks.

52.5 BIOPHYSICAL PROPERTIES AND VIRUS INACTIVATION

In general SRSVs, astroviruses, caliciviruses, and Hepatitis A virus are resistant to lipid solvents, detergents, extremes of pH, and moderate temperatures. All are sensitive to free chlorine or hypochlorite solution; their properties are shown in Table 52–2. Viruses that infect and multiply in mucosal cells of the gastrointestinal tract are acid-stable. This is an important property that allows these viruses to pass through the stomach before reaching the small intestine. As a result of their acid stability, they will survive food processing and preservation conditions designed to establish the low pH that inhibits bacterial and fungal food-spoilage organisms. SRSVs have not been propagated in cell culture; much of our knowledge on their biological properties is derived from human volunteer studies. In one such study, an SRSV (Norwalk virus) retained its infectivity after exposure to pH 2.7 for 3 hours at room temperature. It was also shown to be stable after treatment with 20% ether at 40° C for 18 hours.[71] Like most viruses, SRSVs, astroviruses, caliciviruses, and Hepatitis A retain infectivity after refrigeration and freezing and outbreaks of SRSVs and Hepatitis A relating to frozen foods are well documented. It is noteworthy that those food storage conditions selected for their inhibition of bacterial and fungal organisms are ideal for the maintenance of virus infectivity. All of the above viruses are inactivated by normal cooking processes, but SRSVs in particular are not always inactivated in shellfish after minimal heat treatment. Volunteer studies demonstrated that one strain of SRSV (Norwalk virus) was not inactivated when heated at 60° C for 30 minutes. Additionally, it is unclear whether this virus would be completely inactivated after many pasteurization processes. Studies in the UK have led to recommendations that the internal temperature of shellfish meat should be raised to 90° C and maintained for 1.5 minutes to inactivate Hepatitis A virus.

SRSV survive well on inanimate surfaces, as demonstrated by the persistent outbreaks that have been documented in hospitals, residential homes, and particularly on cruise ships. Although chlorine-based disinfectants are the choice for decontamination of environmental surfaces and are effective for all enteric viruses, SRSVs are resistant to 3.75 to 6.25 mg chlorine l^{-1} which is equivalent to free residual chlorine of 0.5–1.0 mg l^{-1} present in drinking water. SRSVs are inactivated by 10 mg chlorine l^{-1}, and this is more than is required to inactivate polio virus or human rotavirus.

52.6 MODES OF TRANSMISSION

52.6.1 Person to Person

SRSV. Human transmission of SRSVs occurs through the fecal/oral route and has been convincingly demonstrated by the American volunteer studies.[115] An infectious dose as low as 10 to 100 virus particles is considered sufficient to initiate infection. Despite these observations and the lack of evidence for secondary spread by the respiratory route, it is clear that many of the explosive outbreaks described cannot be solely due to fecal/oral transmission. Electron microscopy studies have shown that SRSVs can be detected in vomitus[30,34] and the projectile vomiting associated with acute infection is an additional explanation for the transmission of SRSVs, either from aerosolized virus or through the contaminated environment, and has been emphasized in a number of recent reports.[31,33,34,44,105,204] The high energy associated with projectile vomiting induces aerosolization of virus particles and would disseminate infectious virus into the immediate environment. This, in conjunction with the low infectious dose, allows the spread of infection to secondary contacts and would explain the acute, explosive outbreaks that are commonly documented in semiclosed communities. Environment contamination through the dissemination of infectious vomit is particularly important to the transmission of

Table 52–2 Biophysical Properties of Foodborne Viruses

			Inactivation by:				
Virus	*Nucleic Acid*	*Size*	*pH≤3*	*Ether-Chloroform*	*Alcohol 70%*	*60° C**	*Free chlorine ≥ 10 mg l^{-1}*
SRSV[†] Norwalk/ Norwalk-like	RNA	32 to 38 nm	No	No	Partially	No (30 min)	Yes
Calicivirus	RNA	32 to 38 nm	No	No	Partially	No (30 min)	Yes
Astrovirus	RNA	28 ± 1 nm	No	No	Yes	Yes (10 min)	Yes
Hepatitis A	RNA	27 to 32 nm	No	No	Yes	No (60 min)	Yes

SRSVs in food premises. The natural history of SRSV infections should now include not only person-to-person spread by the fecal/oral route, but also mechanical transmission (hand to mouth) arising from projectile vomiters who have contaminated the immediate environment. The likelihood of spread arising from the inhalation of aerosolized virus by contacts in close proximity to the index case has been suggested but not proven definitively.[31]

Calicivirus, Astrovirus, and Hepatitis A. Person-to-person spread through the fecal/oral route is considered the major mode of spread for all these viruses. Vomiting as a vehicle for transmission has not been demonstrated. Hepatitis A is also excreted in urine and this can represent an additional dimension for spread to close contacts.

52.6.2 Foodborne Transmission

Outbreaks of nonbacterial gastroenteritis have occurred in a wide range of defined settings, such as holiday camps, cruise ships, health care services, schools, and nursing homes where the identification of the mode of transmission is not always possible. Many of these outbreaks result from person-to-person spread through the fecal/oral route or by mechanical transmission (hand/mouth) from the contaminated environment. Projectile vomiters have an important role in the dissemination of infectious virus (SRSVs) by aerosolization that in turn contaminates the immediate environment. Air currents within a confined area will compound the spread of the aerosols generated by symptomatic patients.[31,33] All these factors explain the explosive outbreaks that have been recorded in the literature.

In addition to the mode of spread of SRSVs described above, there are clearly other transmission routes that give rise to point source outbreaks. These will include transmission of SRSVs through the food chain, and current evidence suggests that this mode of spread, although not quantifiable, is significant and of considerable public health importance. Although foodborne SRSV viral gastroenteritis is the most significant viral problem to the food industry, it is also clear from the literature that Hepatitis A has been commonly reported while other viruses, such as the astroviruses and caliciviruses, are only rarely incriminated in foodborne incidents.

Shellfish. The cultivation of bivalve mollusks is a major industry worldwide. Many of the estuaries and inlets used to cultivate shellfish also are used for sewage disposal. Filter-feeding bivalve mollusks concentrate sewage and retain human microbes present in the sewage. Depuration processes are known to be ineffective in removing human viruses from contaminated shellfish and, as a result, significant public health problems arise from human consumption of the raw or undercooked product.[45,124,221]

Many outbreaks of viral gastroenteritis implicating raw shellfish have been described from Europe,[6,37,46,78,98,144] the US,[41,43,74,127,173] Japan,[122] and Australia.[175,176] One of the largest outbreaks associated with raw shellfish occurred in Australia where more than 3,000 people were affected.[175,176] Recent studies in Japan[122] identified 715 foodborne outbreaks out of a total of 908 outbreaks investigated; raw oysters accounted for 45% of these foodborne outbreaks. SRSVs were identified as the commonest virus, accounting for 92% of all viral foodborne outbreaks in this study. In many outbreaks, it was recognized that the shellfish had been harvested from sewage-contaminated waters. The total reported burden of gastroenteritis associated with the consumption of shellfish in England and Wales between 1981 and 1990 is shown in Figure 52–9. It is apparent from these data and from laboratory investigations that viral gastroenteritis is the predominant risk factor associated with eating shellfish. Outbreaks of shellfish-associated viral gastroenteritis in the UK and worldwide in which a pathogen has been identified have been shown to be predominantly caused by SRSVs, which identifies this group of viruses as a major cause of foodborne viral gastroenteritis.

It is also apparent that in many shellfish-related outbreaks a pathogen is not identified. It is worth considering the reasons for these observations as most patients in these outbreaks present with symptoms, which are consistent with viral gastroenteritis if the Kaplan criteria are used to assess the etiology of an outbreak.[120,121] It is well recognized that many outbreaks of shellfish-associated gastroenteritis are either reported too late, or not at all, for appropriately timed clinical samples to be submitted to allow definitive laboratory investigations to be carried out. Furthermore, not all laboratories have the expertise or electron microscopes to achieve a diagnosis in affected patients, and often samples are submitted too late to allow optimal detection of SRSVs. It follows from this that most, if not all, of these outbreaks of gastroenteritis of unknown etiology are likely to be due to SRSVs, which further emphasizes the importance of this group of viruses in shellfish-associated human disease. The recent development

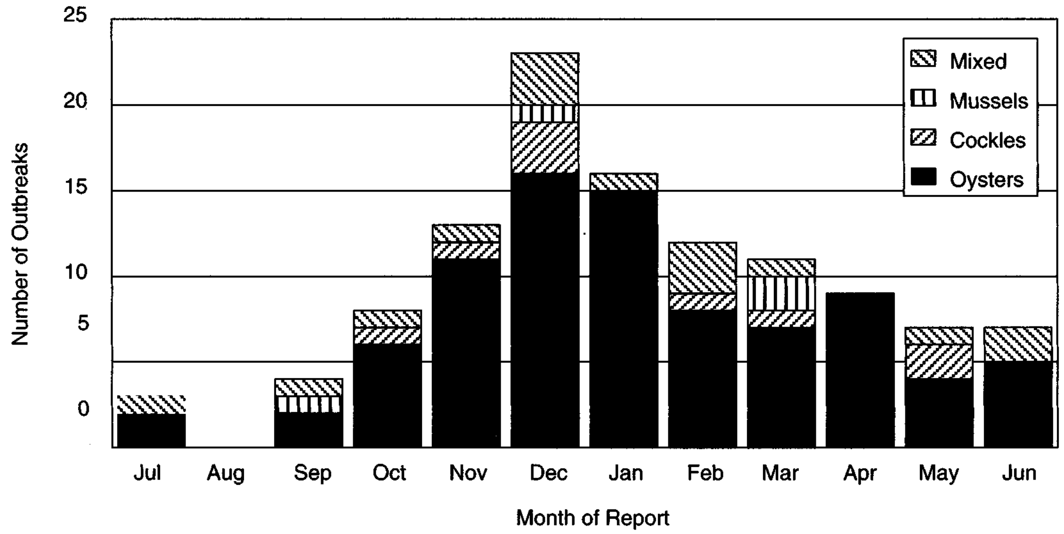

Figure 52–9 Outbreaks of Viral Gastroenteritis due to Molluskan Shellfish in England and Wales 1981–1990

of more sensitive molecular methods for the detection of SRSVs[34,50,113,139] will resolve this problem in the future. Thus, the available data represent considerable under-reporting, at least in the UK, but probably throughout the world.

The epidemiological evidence that uncooked or partially cooked shellfish represent a significant risk to man is now overwhelming. In spite of this, it is apparent that the number of human cases of viral gastroenteritis arising from eating shellfish is an underestimation of the actual problem. Until recently, this was partly due to the difficulties associated with the laboratory diagnosis of SRSVs by electron microscopy, which is relatively insensitive. With the recent molecular characterization of SRSVs has come the real possibility of improving detection methods for this difficult group of viruses. Historically it has not been possible to detect SRSVs in contaminated shellfish because of the insensitivity of electron microscopy. The application of the PCR to extracts of shellfish has now shown that contamination with SRSVs and other enteric viruses can be demonstrated.[12–14,79,143,144,146,147,212,219,233] Furthermore these molecular techniques can be used as powerful epidemiological tools to monitor the spread of SRSVs in contaminated shellfish to the general population and vice versa.[79,212] Recently, elegant molecular epidemiological studies in the US have shown that shellfish grown in clean waters were contaminated by a fisherman who had an acute, explosive episode of diarrhea in close proximity to the oyster bed. Sequencing data from the RNA polymerase region of SRSVs isolated from the fisherman and from patients who subsequently ate the contaminated oysters showed that the isolates were identical.[79] These are the first studies to be reported on the use of molecular epidemiology to monitor the spread of SRSVs in contaminated shellfish through the community and demonstrate one application for this technology. Future studies using molecular techniques will increase the detection of SRSVs in human fecal samples from outbreaks of shellfish-associated nonbacterial gastroenteritis and will reduce the number of outbreaks where an etiological agent has not been identified.

Shellfish contamination arising from polluted water also has been well documented with Hepatitis A virus. Numerous outbreaks have been recorded in the UK, the US, and other parts of the world.[39,53,67,95,96,164,168,200] In the years 1980–1981, seven shellfish-associated outbreaks of Hepatitis A occurred in the UK. The largest outbreak of Hepatitis A arising from the consumption of contaminated shellfish was recorded in Shanghai in 1988.[95] This resulted in over 30,000 reported cases of Hepatitis A in young adults who ate uncooked clams grown in polluted water. Hepatitis A transmission from shellfish is now rare in the UK as a result of heat treatment of cockles prior to being sold to the consumer.

In addition to shellfish, two outbreaks of Hepatitis A resulting from contaminated raspberries have also been documented in the UK over a 12-year surveillance period.[6] Recently, an outbreak of Hepatitis A related to contaminated strawberries[169] occurred in Michigan where 153 students and teachers became ill. It was considered that as many as 9,000 youngsters and adults in Los Angeles may also have been exposed. The contaminated strawberries originated from Mexico and may have been contaminated at source. Additionally, an unusual outbreak of Hepatitis A in the UK relating to bakery products (bread) that affected 50 people also has been reported.[226]

Shellfish-associated outbreaks of astroviruses and caliciviruses also have been documented but only rarely. In one oyster-associated outbreak involving 39 naval officers, one-third developed diarrhea within 4 days of eating the oysters. Astroviruses were detected in stool samples from 5 affected patients and IgM antibodies were present in two patients.[30]

Presumably, reports on foodborne astrovirus and calicivirus infections are rare because of the high level of immunity in the general population. Thus it is clear that any of these viruses can be transmitted to man and resultant disease or resistance is dependent on previous exposure and immunity from childhood infection. SRSVs are the single exception where immunity is short-lived,[34,115,186] and reinfections commonly occur. This explains the significant role of SRSVs in foodborne viral gastroenteritis.

Food Handlers. Outbreaks of viral gastroenteritis caused by SRSVs have also commonly involved the contamination of raw or cold food by an infected food handler; this appears to be a widespread occurrence worldwide.[6,32,37,52,53,79,92,97,121,122,133,134,154,156,190,197,223,227] A wide range of foods has been implicated in foodborne outbreaks that have been extensively reviewed[32,52–54,79,92,97,115,121,122,134,156,223] and include salads, bakery products, sandwiches, hamburgers, fresh fruit, cold meat, and other cold foods. The source of this contamination has often identified a symptomatic food handler in these outbreaks.[38,190,197] The available evidence strongly suggests that those food items that require the most handling present the greatest risk. Surveillance of foodborne outbreaks in Minnesota identified 51 outbreaks over a 10-year period between 1981 and 1991. Contaminated cold food items were identified as a source in 45 (88%) of these outbreaks.[97] Overall a food handler source was identified in 74% of foodborne outbreaks of viral gastroenteritis in Minnesota. The importance of point source outbreaks is that the secondary attack rate is often high (>50%), which in turn amplifies the original foodborne outbreak.

The high infectivity of SRSVs and their potential for infecting large numbers of people through the food chain also has been demonstrated by an outbreak in a bakery[133] where a food handler, who was symptomatic while working, contaminated a large batch of butter cream frosting, which was used to make 10,000 frosted food items. Human consumption of these food items gave rise to 3,000 cases of viral gastroenteritis. In a recent occurrence in the UK, an infected food handler prepared a custard mix that was used to make custard slices. More than 100 people who consumed these custard slices developed viral gastroenteritis (SRSV), and it was concluded that as many as 2,000 people may have been affected (unpublished).

Outbreaks arising from food handlers who become ill after preparing or serving an implicated meal also have been reported.[154] Such outbreaks have also been documented where food handlers were apparently asymptomatic or convalescent from an episode of gastroenteritis.[227] As a result, it is not always clear in every outbreak how food handlers transmit SRSVs through the food chain. Pertinent to these questions is the natural history of SRSV infections in man. The spectrum of illness in affected patients can range from a mild, self-limiting infection to a more severe clinical presentation. Vomiting is a significant symptom and can occur in more than 50% of affected patients. As a result, there is considerable potential for symptomatic food handlers to contaminate (vomit) the immediate working environment or adjacent area (ie, rest rooms or toilets). This environmental contamination would then represent a source of contamination and infection to other food handlers. There is a strong possibility that, in these circumstances, mechanical transmission (hand/mouth to food) might occur, and given the high infectivity of SRSVs, this could explain those outbreaks involving food handlers who were not ill. Whatever the exact mechanism of transmitting SRSVs is, in truly asymptomatic food handlers, these occurrences are a minority and most of the outbreaks described have identified a food handler who was ill at the time of preparing the food or had been ill shortly before. It is also acknowledged that symptoms can be so mild that food handlers may not recall any illness but they would, nevertheless, be highly infectious. Outbreaks relating to food-handlers who are convalescing from gastroenteritis are rare, but this emphasizes the need for food handlers to remain at home for at least 48 hours after recovery from the original illness.

Prospective studies in Bristol, UK, over a 6-year period have shown that approximately 23% of all

SRSV laboratory-confirmed outbreaks are food related.[32] Statewide surveillance data from Minnesota suggested that of the 34 foodborne outbreaks that occurred over a 3-year period (1981–1983), 12 (35%) were caused by SRSV.[97] Recent national surveillance data in the UK for a 2-year period (1992–1993) documented 1,275 outbreaks of gastroenteritis where 50% were considered to be foodborne (639 outbreaks) and show that SRSVs accounted for the majority of the viral (47 outbreaks) foodborne outbreaks (Figure 52–10). This study identified that a food handler was suspected of contaminating the food in 14 of the 41 outbreaks caused by SRSVs.[156] Thus the variation in foodborne outbreaks documented by different workers in the world may reflect the particular interests of those workers. The difficulties of ascertainment, investigation, and laboratory diagnosis all contribute to the under-reporting of foodborne viral gastroenteritis, which is recognized by most workers in the field. Thus, in addition to outbreaks arising from person-to-person spread and mechanical transmission from the contaminated environment, SRSVs are also commonly associated with point source outbreaks. It is now clear that in many cases a likely food vehicle for transmission, other than shellfish, has been identified.

Food handlers also have been identified in the transmission of Hepatitis A to food that was not subsequently cooked further. In one incident a food handler was identified as the source of a foodborne outbreak on a floating restaurant in Florida,[155] and in a separate incident in the UK, bread was incriminated that was thought to have been contaminated by a food handler.[226] Extensive foodborne outbreaks also have been documented in a hospital in Vermont[217] and at a Naval training center in San Diego.[107] In one outbreak in Jefferson County, Kentucky, 202 cases of Hepatitis A occurred after exposure to contaminated green salads,[202] and in a further outbreak 54 people became ill after eating in a restaurant in Tennessee. The source of this latter outbreak appeared to be a food handler who was an intravenous drug abuser.[39] All of these outbreaks of Hepatitis A involve a diversity of foods and emphasize that contamination can occur through any food that is handled either without cooking (raw) or after cooking by an infected food handler.

Surveillance of Hepatitis A outbreaks in the UK has identified seven outbreaks involving a food handler over a 12-year period. The main problem in food handlers is that infected individuals are excreting high levels of virus prior to the onset of classical signs and symptoms of hepatitis infection, and transmission may therefore occur before intervention measures can be instigated. The transmission of astroviruses and caliciviruses by an infected food handler has not been definitively demonstrated to date.

Waterborne Transmission. Transmission of SRSVs, caliciviruses, astroviruses, and Hepatitis A infections to man through the waterborne route have not been definitively demonstrated in the UK. In contrast, contaminated water supplies in America such as municipal water, semi-public water, drinking water on cruise ships, recreational swimming water (lake or pool), and commercially produced ice cubes, all have been incriminated in SRSV outbreaks.[18,28,65,91,97,115,121,142,172,230] A number of point source outbreaks of Hepatitis A also have been described by American workers as a result of fecally contaminated drinking water.[106,174] There is considerable interest in establishing the importance of waterborne infections in the UK and Europe and the application of molecular technology will provide definitive data in the future.

52.7 LABORATORY DIAGNOSIS

52.7.1 Electron Microscopy

Historically, electron microscopy has been the major tool used for the examination of clinical samples from patients with viral gastroenteritis and has had a major role in elucidating the etiology of this syndrome. It is not used for the examination of patients with viral hepatitis (Hepatitis A) because maximum fecal excretion occurs before the onset of jaundice and the virus has no distinguishing features in the electron microscope to allow separation from other small, round, featureless viruses (picornaviruses and parvoviruses) present in fecal samples. The diagnosis of Hepatitis A infections in man has been traditionally made by serological methods (see Section 52.9). It must be emphasized that electron microscopy cannot be used for the detection of viruses in food as it is too insensitive.

SRSV. Currently, electron microscopy is the most commonly used laboratory diagnostic method for the direct detection of SRSV in stool samples. All SRSVs are indistinguishable in the electron microscope when examined by standardized negative staining methods (1.5% phosphotungstic acid pH 6.5). Virus particles possess an amorphous surface structure, lacking a defined symmetry, with a ragged outline (Figure 52–11B). This ragged outline prob-

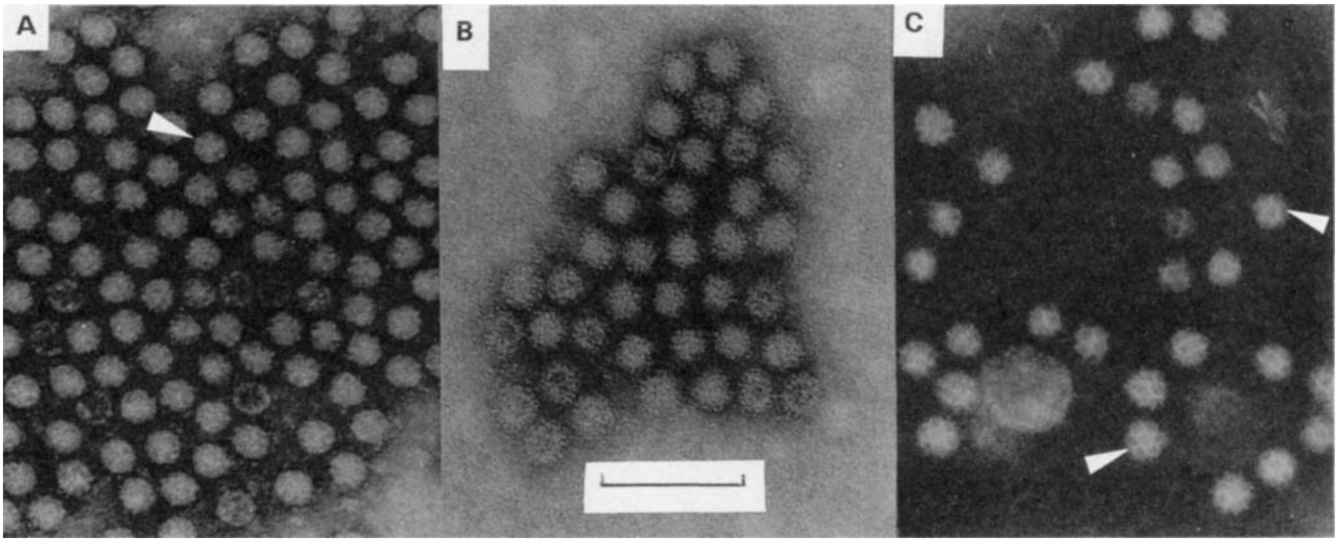

Figure 52–11 Electron Micrograph of Small Round Fecal Viruses. **A**, Astrovirus (arrow indicates surface "star" morphology); **B**, SRSV (Norwalk-Like); **C**, Classical calicivirus (arrows indicate surface cups). All stained with 1.5% phosphotungstic acid pH 6.5. Bar = 100 nm.

ably explains the wide range of particle diameters (32 to 38 nm) described. It is essential that preparations of SRSV are examined in the absence of antibody, because its addition can lead to masking of the surface structure of virus particles and inappropriate identification.[30,36] SRSVs commonly are excreted in stool samples as small aggregates and at low levels, often below the number that can be detected by the electron microscope (10^6 viruses g^{-1} of stool) and this necessitates detailed and careful examination of electron microscopic preparations. Contamination with nonviral proteins in clinical samples often obscures SRSVs and this can be overcome by applying the method of solid phase immune electron microscopy (SPIEM) using human convalescent sera.[37] Samples prepared in this way are far superior to conventional methods of virus concentration used in electron microscopy and increase the detection rate of SRSVs significantly.

Recent comparative studies have shown that overall SPIEM is almost as sensitive as molecular methods for detecting SRSVs[8] with the added advantage of speed that is so important to the management of foodborne outbreaks. Electron microscopy also has the added value of being a catch-all system where all viruses associated with gastroenteritis can be detected. It is likely that electron microscopy will retain an important role in the investigation of human stool samples from foodborne SRSV outbreaks where rapid diagnosis is a prerequisite.

Antigenic Variation. Cross-challenge studies in volunteers have demonstrated that Norwalk and Hawaii viruses are antigenically distinct.[115,218,231] Further human volunteer studies using the Montgomery County agent and Norwalk virus identified a one-way cross protection. These early studies also demonstrated that a short-term homologous immunity occurred after challenge in humans with all three viruses.[70,115,231] Long-term immunity to homologous challenge has only been demonstrated in some patients,[186] and this unusual aspect and complexity of the immunobiology of SRSVs is currently under investigation.[115]

The antigenic relatedness of Norwalk, Hawaii, and Snow Mountain viruses has been studied by assessing the pattern of sero-responses in volunteers.[115] Using an EIA assay variable degrees of antigenic relatedness were observed, with a two-way cross-reaction between Snow Mountain and Hawaii viruses and a one-way cross-reaction between Norwalk and Snow Mountain viruses documented.[115] These results may reflect heterologous responses and contrast with the greater specificity of IEM or SPIEM, where relatedness is based on intact virions and capsid epitopes.

Using immune electron microscopy (IEM or SPIEM), four SRSV antigenic types have been identified in the UK[139,149,150] and six in the US,[151] while Japanese workers have identified nine serotypes.[183] Recent suggestions are that the nine Japanese serotypes may include similar viruses on the basis of cross-reactions and may therefore be an overestimate of the actual number of distinct serotypes. Definitive data on the antigenic relationship of SRSVs will have to await the development of specific monoclonal antibodies rather than human convalescent or hyperimmune sera that are more broadly reactive. This is a reality now that some strains of SRSVs have been completely sequenced and will allow the production of baculovirus expressed viral proteins and the development of monoclonal antibodies. In spite of these difficulties, SPIEM has been extremely rewarding in defining the changing prevalence of different SRSV antigenic types in the UK and for identifying appropriate isolates for molecular characterization.

Calicivirus. Human enteric caliciviruses originally were described in fecal samples using negative staining techniques.[161] This family of viruses possesses a unique morphology. Classical particles viewed along their threefold axes of symmetry possess a central, stain-filled cup (calices) surrounded by six peripheral cups giving rise to a Star of David appearance (Figure 52–11C). Calicivirus particles viewed along their twofold axes of symmetry possess four cups and also are identifiable definitively. Particles viewed along their fivefold axes present as a 10-pointed sphere and may not be so readily identified as the classical particles described above. Unlike astroviruses, which possess a smooth entire edge, caliciviruses possess a ragged outline that makes accurate measurements difficult. This explains the particle diameters of 31 to 38 nm quoted by most workers.

This unique morphology allows definitive calicivirus identification by electron microscopy,[160] but electron micrographs always should be taken to record observations made from viewing specimens in the microscope and allow more detailed inspection. This unique calicivirus morphology is the only acceptable criterion for identifying the classical human caliciviruses and any divergence from this morphology is not acceptable. Occasionally, difficult specimens arise and when the morphology is suggestive of a calicivirus, but not convincing, then replicate samples should be prepared and re-examined. Electron microscopy is currently the only routine method available for laboratory diagnosis and requires skilled operators to achieve consistently reproducible results.

Antigenic Variation. Human enteric caliciviruses possessing classical morphology have been grouped into four distinct antigenic types by IEM and share a common antigen detectable by RIA.[57,59]

Astrovirus. Astroviruses originally were recognized by Madeley and Cosgrove in 1975[162] and subsequently described in detail a few years later.[160] These workers coined the term astroviruses as a result of the characteristic six-pointed star morphology (Figure 52–11A), which is resolved on the surface of virus particles by electron microscopy following negative staining. The negative stain (1.5% phosphotungstic acid pH 6.5) used in electron microscopy is important for the consistent resolution of the surface star. Astroviruses are remarkably uniform in size measuring 28nm (± 1nm) in diameter and possess a smooth, entire, sharply delineated outer edge. The characteristic star-shaped surface morphology, which is enhanced in high-contrast micrographs, is present on 10% to 20% of particles and is diagnostic, allowing definitive morphological differentiation from calicivirus with which they have been confused. Often astroviruses are present in large numbers in electron microscopical preparations made from samples collected during the acute phase of the illness. Naturally occurring, large or small aggregates are common and probably arise from the release of crystalline arrays from infected cells that have lysed. The possibility that these virus aggregates result from antigen/antibody complexes (copra antibody) has not been confirmed and is an unlikely explanation. Procedures used in the concentration of astroviruses from clinical samples prior to examination by electron microscopy are important. Astroviruses are unstable if they are pelleted from cesium chloride gradients but purification and stability in tartrate/glycerol gradients prior to examination by electron microscopy have been demonstrated.[10]

Difficulties arise in the identification of astroviruses if IEM is applied. Antibody-mediated aggregation of astrovirus particles in suspension masks the typical star-shaped surface structure and leads to inaccurate identification as demonstrated by the original classification of the Marin County agent as a Norwalk-like virus.[184] In contrast, the capture of astrovirus particles onto antibody-coated electron microscope grids (SPIEM) is an elegant and highly sensitive method of identification and has allowed the diversity of astrovirus capsids to be subtyped into seven serotypes.[135] The major disadvantage of immune electron microscopy is its high specificity in comparison with direct electron microscopy, which remains the only catch-all technique available for all diarrhea viruses.

Antigenic Variation. Studies in Oxford, England, using SPIEM and immunofluorescence identified six antigenically distinct astroviruses over a 10-year period.[135,145] Serotyping of 165 strains documented serotype 1 as the most prevalent strain (64%). The authors also demonstrated that the frequency of the other serotypes varied from year to year. Since this report, one additional serotype has been recognized. Herrman and colleagues recently have developed a monoclonal antibody enzyme-immunoassay and have confirmed the antigenic variation described by the Oxford Group.[100]

52.7.2 Enzyme-Immunoassay (EIA)

The need to develop alternative assays for the detection of human small round viruses in stool samples has been recognized by many workers. Japanese workers developed a solid-phase RIA using a hyperimmune guinea pig serum and demonstrated that this assay was more sensitive than electron microscopy for the detection of caliciviruses.[177] Subsequently, these workers converted this assay to an EIA that had a similar sensitivity.[179] These assays are not yet commercially available, but will presumably be available in the future for investigating clinical samples.

Recent studies have described the identification of an astrovirus group antigen that is shared by five of the known astrovirus serotypes. The preparation of monoclonal antibodies to the group antigen allowed the development of an EIA, which detected all astroviruses grown in cell culture.[100] More recently, these workers have modified their EIA to detect astroviruses in stool samples[101] and have compared this assay with IEM. Their studies have shown that the EIA has comparable sensitivity and specificity to IEM and it is likely that this assay will eventually replace electron microscopy in diagnostic laboratories. The assay will allow more extensive studies to be carried out in the future on clinical samples and will enhance our knowledge on the epidemiology and medical importance of astroviruses.

More recently, the molecular characterization of Norwalk virus and other SRSVs has allowed the expression of capsid proteins in a baculovirus expression system.[50,68,111-113,139,148] The use of these reagents has resulted in the preparation of specific antibodies for use in an antigen capture EIA.[81,112] Preliminary results suggest that these assays are serotype specific and represent a major advance in the development of alternative assays to electron microscopy for the detection of SRSVs. Nevertheless, it is unlikely that any of the above EIA developments will be sufficiently sensitive for use in the direct detection of viruses in food incriminated in foodborne outbreaks of viral gastroenteritis or viral hepatitis.

52.7.3 Molecular Diagnosis

SRSV and Calicivirus. With the complete sequencing and characterization of the SRSV and calicivirus genome[68,113,139] has come the prospect of applying molecular techniques to clinical diagnosis and transmission patterns[88,123] and possibly to the detection of viruses in food. Although methods now have been described where the PCR has been applied to the RNA polymerase region of SRSVs, continual refinement and design of new primers have been necessary because of the diversity of this group of viruses. Studies to date, surprisingly, have demonstrated that the RNA polymerase region of SRSVs shows considerable heterogeneity and that SRSVs can be classified into two genotypes.[3,50,85-87,225] Thus a continual assessment of SRSVs at the molecular level may be necessary at least in the short term. Molecular epidemiology and the sequencing of SRSV strains will be a powerful tool in future investigations of point source outbreaks particularly for the examination of shellfish[3,13,14,35,50,144,147,169,212] and possibly other implicated foods and in monitoring spread of SRSVs between hospitals.[88] Because foodborne outbreaks caused by classical caliciviruses are rare, the development and application of primers for this virus are less urgent than for SRSVs. These techniques currently are restricted to the research laboratory but future developments will ensure an important role in routine diagnosis from clinical samples where they will complement electron microscopy. An important future requirement is the removal of PCR inhibitors from stool samples to ensure maximum sensitivity.

Astrovirus. The complete sequence of one strain of astrovirus has been published,[228] but the application and potential for molecular diagnosis has not yet reached diagnostic laboratories. A sensitive dot-blot hybridization procedure for detecting astroviruses in fecal samples has also been described[229] but has not been validated in comprehensive field studies.

Molecular technology, although difficult, is likely to be the only method by which any of these viruses, as well as Hepatitis A, can be detected directly in food or water samples incriminated in outbreaks. The method has the additional benefit of allowing precise fingerprinting of the virus by sequence analysis, thus providing definitive molecular evidence of the role of any of these viruses in human foodborne outbreaks.

52.8 VIRUS ISOLATION

52.8.1 SRSV

At the time of writing, there are no reports that document the isolation of SRSVs in either cell or human intestinal organ cultures. Developments in this area clearly are needed to study the cell tropism, cellular receptocytes, and viral replication of this important group of viruses. However, it is unlikely that isolation in cell cultures will ever be used as a method for diagnosing infected individuals or for the examination of food samples as in vitro methods are too slow and labor intensive.

Numerous studies in a wide range of animals have failed to identify a suitable model.[115] Some success has been achieved with the transmission of Norwalk virus in chimpanzees where serological responses and the excretion of Norwalk antigen in stool samples was described,[115] but animals have no role in diagnosis of foodborne infections.

52.8.2 Calicivirus

In contrast to the serial propagation of astroviruses in trypsin-containing media, similar attempts to isolate calicivirus have failed. A single report documents that human enteric caliciviruses produced a nonproductive infection in dolphin kidney and in human embryonic kidney (HEK) cells in the presence of trypsin.[57,58] Cytoplasmic replication was demonstrated by immunofluorescence and by radio-labeling experiments. This report has not been confirmed, and many other workers have failed to propagate human caliciviruses in vitro.

52.8.3 Astrovirus

Initial studies demonstrated that astroviruses undergo an incomplete replication cycle in HEK cells, but serial passage was unsuccessful. The addition of trypsin in serum-free medium has allowed the replication of a productive infection with release of infectious progeny virus that can be serially passaged.[135] In the absence of trypsin, astrovirus replication results in the production of a 90,000 molecular weight protein in the cell cytoplasm.[50] In the presence of trypsin, this protein is cleaved into three smaller proteins that appear to be essential to the production of infectious progeny virus.[50,229] Serial passage has been reported in trypsin-treated HEK and a continuous line of Rhesus monkey kidney cells (LLCMK2), and more recently in a cell line established from a human colonic carcinoma (CaC0-2).[229] Virus yields in CaC0-2 cells are approximately 2 logs greater than in the former two cell lines. The ability to propagate astroviruses in cell culture allows sero-epidemiological studies to be carried out, but this is not the method of choice for diagnostic purposes or for the examination of food as it is labor intensive, expensive, and likely to be less sensitive than immunologically based assays.

52.9 DIAGNOSTIC SEROLOGY

52.9.1 SRSV

American workers have been successful in using reagents derived from human volunteers to carry out both sero-epidemiology and diagnostic serology in outbreaks of Norwalk virus.[115] The development of an RIA, EIA, and immune adherence assay (IAHA) has greatly facilitated study of the natural history of Norwalk virus infections and has provided compelling evidence on its etiological role in epidemic gastroenteritis in the 1970s.[115] With the recent molecular characterization of SRSVs, reagents derived from humans and experimentally infected animals will have a limited future utility.

The expression of Norwalk virus capsids in baculovirus vectors has been used in the development of an EIA for the identification of Norwalk virus antigen and antibody in naturally occurring or experimentally induced infections.[83,115,218] However, the demonstration of high prevalences of Norwalk virus antibody in recent serological studies using these baculovirus expressed viral proteins[83] has produced results that are difficult to interpret because Norwalk virus is no longer circulating in the community. The possibility that this assay is detecting heterologous responses should be considered. In general, the development and application of reagents arising from the molecular characterization of recent isolates of SRSVs will considerably advance our knowledge of the epidemiology of foodborne infections as they will represent currently circulating strains of SRSV. However, it is unlikely that methods directed toward a serological diagnosis will be useful in diagnostic laboratories in the future to investigate foodborne infections where rapid diagnosis is required for establishing the etiology of the outbreak and for the instigation of control measures. They will, however, be useful for retrospective diagnosis and establishing the etiology of an outbreak.

52.9.2 Calicivirus and Astrovirus

Serology has been applied to the diagnosis and confirmation of both calicivirus and astrovirus infections. Studies have shown that IgM responses or rising titres (IgG) occur following calicivirus infection[47,57,62–64,179] and astrovirus infections in children.[11,135] These techniques, although useful in epidemiological studies, are not ethically justified for the diagnosis of enteric diarrhea virus infections in young children, particularly as other noninvasive and sensitive methods such as electron microscopy and PCR are available for rapid diagnosis.

52.9.3 Hepatitis A

Diagnostic serology is the standard method used universally for the diagnosis of Hepatitis A infections in man. The demonstration of Hepatitis A specific IgM in early acute/convalescent serum samples is a reliable and sensitive method and has provided an important diagnostic assay for establishing the importance of Hepatitis A within the viral hepatitis syndrome in man. The demonstration of abnormal liver function tests in serum samples complements the specific IgM assay. Assays for the detection of IgM also have been developed for urine and salivary samples; these have facilitated the investigation of outbreaks.[110,187] Sero-prevalence studies directed toward the detection of specific IgG also have been used widely in many countries as the mainstay of Hepatitis A epidemiology.[17,77,103,104,108,126,185,208]

52.10 PREVENTION AND CONTROL

SRSV viral gastroenteritis and hepatitis A are the most important viral causes of foodborne disease in man. Other viruses such as astroviruses, caliciviruses, and, to a much lesser extent, rotaviruses, are extremely rare as a cause of foodborne illness. It is apparent that all these enteric viruses do not replicate in food or water and their presence in the food chain is directly related to human fecal contamination.[52] This is true of shellfish grown in polluted waters, drinking water contaminated by human sewage, or the mechanical transmission of these viruses into food directly by infected food handlers. It follows that prevention and, therefore, control of these foodborne infections[6,37,38,66] can be interrupted by the food and shellfish industry given an appropriate level of education and a change in current practices. This will include changes necessary to reduce contamination of the environment through sewage disposal.

52.10.1 Shellfish Transmission

The bivalve mollusks (shellfish) are clearly a major source of outbreaks of foodborne transmission of viral gastroenteritis in developed countries and, to a lesser extent, Hepatitis A. Attempts to grow shellfish in clean waters (sewage free) have been occasionally instigated and this action will remove all enteric viruses and will significantly reduce this public health hazard from the food chain.[79] Unfortunately even when shellfish are grown in clean waters, contamination has occurred through discard of human sewage by local fishermen collecting the shellfish.[79] Thus the education of fishermen collecting shellfish is important to maintain clean oyster beds. It is clear that many shellfish beds are contaminated by sewage and remain a public health hazard; therefore, the shellfish should always be purchased from accredited suppliers to reduce the risk of viral transmission. Current methods of depuration are ineffective in eliminating viral contamination, and cooking shellfish renders them unpalatable to the consumer and has not gained universal favor. Steaming shellfish also has been studied and shown to be ineffective in inactivating SRSVs.[124] Nevertheless, heating shellfish (cockles) in the UK has eliminated Hepatitis A outbreaks. Cross contamination of other foods in the kitchen from contaminated shellfish also is well recognized, and shellfish need to be discarded when food-related outbreaks occur.

52.10.2 Waterborne Transmission

Waterborne transmission as a result of human fecal contamination will presumably continue to occur occasionally in the developed world as a result of processing errors in public drinking water supplies. However, such episodes are fortunately rare within our current knowledge. Shock chlorine treatment (>10 mg l^{-1} for 30 minutes) has been shown to be effective in eliminating infectivity from swimming baths associated with outbreaks of SRSV viral gastroenteritis,[38] and also is effective for the inactivation of Hepatitis A and other enteric viruses. Recent unpublished reports of high levels of astroviruses in bathing seawater in the UK may represent a public health problem but confirmation is urgently needed.

52.10.3 Food Handlers

The other important source of foodborne viral gastroenteritis and occasionally Hepatitis A transmission is the infected food handler. Symptomatic food handlers often have been incriminated in outbreaks of viral gastroenteritis, and they must be excluded from the work environment when symptomatic and for a minimum of 2 days after resolution of symptoms. It should be recognized that susceptible food handlers can prolong the risk in food establishments if other employees are symptomatic, because of the high risk of person-to-person spread. Decontamination of all environmental surfaces within the food preparation area is essential if food handlers have been ill on the premises.[37,38] This should include staff rest areas and toilet facilities. This is necessary to eliminate aerosolized vomit, generated by symptomatic food handlers, which has settled on hard surfaces, as a source of transmission from the contaminated environment. All high-risk foods that have required handling must be discarded following an outbreak among food handlers in a food establishment. The high infectivity of SRSVs, and the explosive outbreaks of gastroenteritis that commonly occur in closed or semiclosed communities, present a major challenge to control of infection and require immediate and aggressive intervention measures.[31,33,44] Transmission and spread of SRSVs occur via the fecal/oral route and by transport of aerosolized virus by air currents generated by projectile vomiting, which results in environmental contamination.[31,37] Measures directed toward the interruption of these modes of transmission must include enteric precautions and exclusion of symptomatic staff, but these alone are ineffective and also should include measures to deal with incidents in which employees vomit on the premises.

Effective hand washing by food handlers is a prerequisite in all settings relating to foodborne viral outbreaks and should be carried out routinely. Staff employed to clean and decontaminate food premises must wear disposable plastic gloves and gowns for cleaning vomit, fecal material (toilets), or contaminated clothing. Masks should be considered in all instances where aerosols are generated. Soiled linen or clothing should be handled carefully to reduce to a minimum the generation of aerosols, and transported in plastic bags for decontamination. All potentially contaminated environmental surfaces including toilets and rest rooms should be disinfected with a chlorine-based product and cleaned with a hot detergent solution.

Volunteer studies on the immunobiology of SRSVs have demonstrated that both short- and long-term protection occurs. Until the mechanisms involved in immunity have been demonstrated and fully understood, it is unlikely that a vaccine can be effective.[115] Effective vaccines have been developed for Hepatitis A virus, and its widespread introduction to those employed in the food industry would essentially eliminate foodborne Hepatitis A transmission by food handlers. This control measure is not currently considered to be cost-effective in the UK, although it has been recommended in America.

A significant and cost-effective measure for the prevention of foodborne viral infections relates to the current level of education among those employed in the food industry. The mechanisms involved in transmission should underpin prevention strategies and should be explained to all food handlers and emphasis placed on the single most important measure of personal hygiene, which includes regular hand washing, particularly after toilet use. Viral gastroenteritis among food handlers needs special attention by those responsible for the management of food safety. The absence of food employees with gastrointestinal sickness, however mild, should be positively encouraged; it should not result in a financial penalty and would be an additional effective measure appropriate to prevention.

52.11 CONCLUDING REMARKS

Analysis of foodborne virus infections from many countries has established that SRSVs are a major cause of epidemic gastroenteritis and their importance relates to the diversity of strains circulating and the lack of long-term immunity, which allows reinfections to occur at regular intervals. Other enteric viruses, such as the astroviruses and classical caliciviruses, predominantly are pediatric infections giving rise to long-term immunity that persists into adulthood and explains the rarity of foodborne incidences arising from these enteric infections. Similar arguments are relevant to rotavirus infections.

Common-source foodborne SRSV infections arise from two distinct situations. It is clear that infected food handlers are a primary cause of foodborne outbreaks and measures to intervene in the transmission chain are particularly relevant to control. The exclusion of food handlers who are symptomatic, however mild, for 48 hours after recovery is paramount as is the decontamination of food premises when outbreaks arise. Education of employees and the application of best practice within the food industry remains an important objective and needs to be promoted. Regular hand washing by food handlers is essential and an important procedure to reduce the transmission of the highly infectious SRSVs.

An equally important mode of transmission of SRSVs is through contaminated shellfish, particularly bivalve mollusks. Ideally, shellfish should be grown in pollution-free water, but this is not always feasible. The accreditation of shellfish beds will go some way toward resolving the hazard to humans but falls short of definitive control. Depuration procedures are known to be ineffective and heat inactivation prior to consumption, although successful for the control of Hepatitis A, renders the product unacceptable to the human palate. Screening of shellfish prior to human consumption using the recently described molecular methods does not inform the producers that infectious virus is present as these methods do not establish the presence of live or inactivated virus. Further research in this area to establish whether a relationship exists between genome detection and infectious virus is clearly required.

Although foodborne Hepatitis A infections are relatively uncommon in the UK, they are well recognized in other parts of the world. Transmission from food handlers can be interrupted by exclusion from the work premises when the employee is symptomatic. Some workers in the US have suggested that food handlers should be immunized, but cost-benefit analysis in the UK does not support this conclusion. Nevertheless it is clear that with the improvements in personal hygiene and the socioeconomic status of the population, sero-prevalence in the UK is declining in some regions and it will be important that surveillance procedures for foodborne Hepatitis A infections are robust in the future. Transmission of Hepatitis A through the human consumption of shellfish remains a problem in many parts of the world and can only be eradicated by propagation of shellfish in pollution-free water or by heat inactivation of the virus.

The increasing use of sewage sludge as a fertilizer and soil conditioner on agricultural land poses new problems in the future for the prevention of foodborne viral infections. Although there are no currently recorded outbreaks of foodborne viral infections associated with the use of sewage sludge on agricultural land, a recent report where rotaviruses and Hepatitis A were detected by ELISA and molecular methods in market lettuce in Costa Rica serves to identify a potential problem.[99] The increasing importation of produce into the UK and elsewhere in the world requires assessment in terms of the risk to the consumer. As the level of potential contamination currently is unknown, this is a clearly identifiable area for risk assessment. In the meantime, thorough washing of products grown on agricultural land where sewage sludge has been used is imperative to the delivery of a safe product. Research in this area is urgently required to determine the stability of human viruses in sewage and the risk to the human food chain. This is an emerging area applicable to the control of human disease and requires robust surveillance procedures throughout the world. Surveillance of foodborne viral infections worldwide generally is poor, and procedures should be taken to improve the detection and reporting of these infections. Only then can a comprehensive picture of human foodborne viral disease become established and better defined.

53.1 INTRODUCTION

53.1.1 Fungi and Food

Fungi are a very diverse group of organisms and have a significant impact on the production, spoilage, and safety of food. Food mycology, as a coherent study, came of age with the appearance of major texts.[11,143,156] Initially, methods for studying fungi in foods were based on those developed in the medical microbiology laboratory, but now more appropriate techniques have been developed and validated at a number of international workshops on the standardization of methods for the mycological examination of foods.[155] It is especially important to use appropriate methodology that will distinguish between superficial contamination of surfaces with propagules such as spores and infection of the interior of a solid substrate with mycelium.

Traditionally mycologists have studied this group of eukaryotic organisms that are now considered to belong to at least two, possibly three, kingdoms. The majority of fungi, in the broadest sense, have in common a heterotrophic metabolism (which distinguishes them from plants and algae) and the presence of an outer wall (which distinguishes them from animals). However, what may now be referred to as the kingdom of "true fungi," which includes the zygomycetes, ascomycetes, basidiomycetes, and deuteromycetes, do not have a motile form at any stage in their life cycles. The oomycetes, which used to be grouped together with the zygomycetes as "phycomycetes," include many very important pathogens of food plants such as the potato blight caused by *Phytophthora infestans*. But, they do have a motile stage in their often complex life cycles, and their biology relates them more closely with some groups of algae now grouped in the kingdom Protista. What have been referred to above as the "true fungi" may well have evolved from the same group of organisms that gave rise to the chytridiomycetes, and it is now widely accepted that the latter should be included in the "true fungi."[2,167] However, the chytridiomycetes do not have a major impact on food mycology except that the group includes *Synchytrium endobioticum*, the causative agent of wart disease of the potato, and *Olpidium brassicae*, a parasite of cabbage roots that may act as a vector for several serious viral diseases. Another disease of brassicas, known as clubroot, is caused by *Plasmodiophora brassicae*, which belongs to yet another phylum with some affinities with the slime molds, also traditionally studied by mycologists.

These groups are summarized in Table 53–1, and even if this classification turns out not to reflect the real evolutionary relationships among the fungi *sensu lato*, the group referred to as the true fungi shows a trend in their biology that is important in their interactions with food. They have shown a steady evolution to increasingly terrestrial environments and to habitats of reduced water activity so that they are able to colonize solid substrates. This evolutionary process has led to the development of two lifestyles—the yeasts and the molds. Despite their apparent morphological simplicity, yeasts occupy niches in which a liquid phase is dominant and contain a rich source of nutrients, such as the nectaries of plants and the body fluids of insects and other animals. They show physiological adaptation to these environments, and many species are auxotrophic for one or more vitamins. Although the matter is still debated,[27] the biology of the yeasts suggests that they have evolved several times from different groups of filamentous fungi. The yeasts are not known to be associated with the production of mycotoxins, although they certainly are important in the spoilage and production of food.

The second lifestyle is the filamentous growth pattern based on the extension of the hyphal tip and the production of a complex branching anastomosing mycelium.[21,80] This mycelium is able to grow over, and penetrate into, complex solid substrates by the secretion of enzymes to degrade macromolecules and the absorption of the small molecules released. This growth form often is associated with the differentiation of specialized aerial hyphae that produce spores well adapted for air dispersal, the study of which forms an important part of air microbiology.[66] Efforts to control food spoilage by molds need to take account of the atmosphere as a persistent source of viable fungal propagules, and the ability of some species to grow at water activities as low as 0.61 (Table 53–2).[37,142]

The filamentous fungi, and their prokaryotic counterparts, the actinomycetes, also produce a diverse range of low molecular-weight compounds referred to as secondary metabolites, many of which are secreted into the environment.

The nature of secondary metabolism and the role of secondary metabolites in the biology of the producing organisms are still topics of active debate,[194] but many of these compounds do have biological activity, such as toxicity to microorganisms (antibiotics), plants (phytotoxins), and animals. When these mold metabolites are toxic to humans and domestic animals and are associated with food, animal feeds, or raw materials used for their production, they are known as mycotoxins.

There are also a number of fungi that produce macroscopic fruiting bodies, which have provided a source of food—mushrooms, boletes, and morels—in many parts of the world. Some species, such as *Amanita phalloides*, the deathcap, produce toxic metabolites in their fruit bodies and may cause illness, even death, if consumed.[129] Amanitoxin, produced by *A. phalloides*, causes irreversible liver and kidney damage with symptoms developing within 10 to 14 hours that may lead to death in 4 to 7 days if not diagnosed and treated. The chemically unrelated orellanin, produced by *Cortinarius orellanus*

Table 53–1 The Major Phyla of Organisms of Interest to the Food Mycologist

Kingdom	*Phylum*	*Examples*
Fungi	Chytridiomycota	*Synchytrium endobioticum* (Potato wart)
	Zygomycota	*Rhizopus stolonifer* (Fruit rots)
	Ascomycota*	*Penicillium*, *Aspergillus* (mycotoxins)
	Basidiomycota*	*Agaricus bisporus* (mushroom)
Protista	Oomycota	*Phytophthora infestans* (potato blight)
	Plasmodiophoromycota	*Plasmodiophora brassicae* (cabbage club root)

*Separation of these phyla is based on details of sexual reproduction. Many important species of molds and yeasts have no known sexual stage and are classified in form genera of the fungi imperfecti such as *Aspergillus* and *Penicillium*.

and related species, also causes irreversible kidney damage, signs of which appear after 3 to 14 days. Earlier symptoms including vomiting may occur within 4 to 9 hours of consumption, however. This species has been responsible for many deaths in parts of Eastern Europe. One of the more bizarre physiological effects is associated with coprine, produced by *Coprinus atramentarius*, which causes great discomfort when consumed with alcohol, a reaction that may be apparent within 10 to 15 minutes. However, because these toxins are a natural constituent of fruiting bodies deliberately ingested, usually as a result of mistaken identity, they are not included as mycotoxins, a distinction based on human biology rather than chemistry, biochemistry, or toxicology.

53.1.2 Mycotoxins in Food and Animal Feeds

Although a very diverse range of molds is able to produce toxic metabolites, and many of these may be important in animal husbandry, there are three genera that are especially important in foods: *Aspergillus*, *Penicillium*, and *Fusarium*. There are many textbooks on mycotoxins, mycotoxicoses, and mycotoxigenic fungi,[12,28,89,118,122,169,171] and the primary literature on these compounds is very extensive. In terms of acute toxicity (Table 53–3), the mycotoxins most commonly encountered in food are about 1 million times less toxic than the most lethal of the botulinum toxins and are significantly less toxic than many of the algal toxins. However, long-term chronic toxicity is of special concern because several of these mold metabolites are carcinogenic and influence the immune response of a number of animal species.

The occurrence of these toxins as contaminants of major components of diets (see Table 53–4) implies that exposure may occur over long periods of time. Although the number of incidents of acute poisoning of farm animals by mycotoxins is significant, the number of cases of confirmed acute mycotoxin poisoning in humans during the last few decades is small compared with the numbers of cases of food poisoning resulting from viruses and bacteria. In the Middle Ages, ergotism, from the production of alkaloids such as ergotamine (Figure 53–1) in cereals by the plant pathogen *Claviceps purpurea*, undoubtedly claimed many lives. At the beginning of this century, two major mycotoxicoses caused considerable suffering and mortality. They were alimentary toxic aleukia in Russia (ATA), a terrible illness caused by the consumption of cereals contaminated with trichothecenes such as T-2 toxin (Figure 53–2) produced by the plant saprotrophs *Fusarium sporotrichioides* and *F. poae*,[83] and yellow rice disease in Japan, associated with a number of toxigenic species of *Penicillium*, especially *P. islandicum*.[61] More recently, a tragic outbreak of aflatoxicosis caused by the consumption of corn contaminated with *Aspergillus flavus* was reported in India involving approximately 1,000 people, of whom nearly 100 died.[87] Undoubtedly, exposure to mycotoxins in the diet contributes to chronic ill health of poorer people in the humid tropics who depend on plant products that are inadequately stored after harvest. In more temperate parts of the world, mycotoxins are thought to cause the chronic kidney disease known as endemic nephropathy.[26]

Several very important mycotoxins, such as the sporidesmins, slaframine, and the tremorgens are associated with animal feeds and forages, but this review will not attempt to cover these although they will have an impact on the quality and quantity of meat and other animal products.[121] In two instances, the presence of mycotoxins in animal feed can lead to their presence in human foods because they pass through the food chain in either their original or metabolized form. These will be dealt with in the sections on aflatoxin and ochratoxin.

Many foods are susceptible to mold growth when stored under inappropriate conditions; a number of

foods have evolved in which mold growth is an essential part of their manufacture (eg, mold-ripened cheeses and sausages, tempeh, and miso). Mycotoxins may be formed in foods, raw materials for food production, or animal feeds, and the production of each mycotoxin usually is limited to a small range of fungal species or even strains within a species. Many mycotoxigenic species are able to produce several mycotoxins, and foods may be contaminated with several species of mold. The biosynthetic pathways leading to the production of mycotoxins are diverse and generally involve either polyketide, mevalonate, or amino acid precursors and mixtures from these three pools of intermediates.[120,173] It is likely, therefore, that contaminated foods will contain a cocktail of toxins that can interact synergistically. For example, Kanisawa[86] described a synergistic effect of citrinin on the carcinogenic activity of ochratoxin A in mice, and Sato and Ueno[157] provided convincing evidence of the synergistic interaction of ochratoxin A and T-2 toxin on their acute toxicity in day-old chickens. Indeed, it is probable that the outbreak of Turkey X disease in 1959, which led to the discovery of the aflatoxins, was really the result of the synergistic interaction between cyclopiazonic acid and aflatoxin.

Although it is essential to recognize the potential for these complex interactions, it is simpler to deal with individual toxins. The following sections will deal with the major mycotoxins in human foods.

53.2 THE AFLATOXINS

53.2.1 Production

Aflatoxin B_1 (Figure 53–3) is the most important of this large family of compounds and is produced by three closely related species: *Aspergillus flavus*, *A. parasiticus*, and the more recently described *A. nomius*.[93] Strains of *A. parasiticus* and *A. nomius*, but not *A. flavus*, also are able to produce aflatoxin G_1 (Figure 53–3). The aflatoxins arise essentially

Table 53–4 Some Major Mycotoxins Found in Foods

Mycotoxin	*Major Foods*	*Common Producing Species*
Aflatoxins	Corn, groundnuts, figs, tree nuts	*Aspergillus flavus* *A. parasiticus*
Aflatoxin M_1	Milk, milk products	(secreted by cow after metabolism of Afl B_1)
Cyclopiazonic acid	Cheese, corn, groundnuts, Kodo millet	*Aspergillus flavus* *Penicillium aurantiogriseum*
Deoxynivalenol	Cereals	*Fusarium graminearum* *F. culmorum*
Fumonisin	Corn	*Fusarium moniliforme*
Ochratoxin	Corn, cereals, coffee beans	*Penicillium verrucosum* *Aspergillus ochraceus*
Patulin	Apple juice	*Penicillium expansum*
Penitrem A	Walnuts	*Penicillium aurantiogriseum*

Tenuazonic acid	Tomato paste	*Alternaria tenuis*
Zearalenone	Corn, barley, wheat	*Fusarium graminearum*

from a decaketide precursor that has undergone extensive rearrangement. The molecular biology of their biosynthesis has been reviewed.[10] *A. parasiticus* is the most toxigenic of the three species, with perhaps 80% to 90% of isolates being able to produce aflatoxins. In the case of *A. flavus*, perhaps only 30% to 40% of isolates on a worldwide basis are aflatoxigenic, but this varies from one part of the world to another and also may be dependent on the substrate from which the isolates were obtained. Some strains of this species have been used in the production of koji and *A. oryzae*, which is most frequently used for koji production and is considered to have evolved from *A. flavus* by continuous industrial use.[44] Both *A. flavus* and *A. nomius*, but not *A. parasiticus*, also produce cyclopiazonic

acid that may act synergistically to influence the apparent toxicity of aflatoxin. Gallagher and colleagues[58] studied a collection of 54 isolates of *A. flavus* and found that 14 produced cyclopiazonic acid and aflatoxin concurrently, 4 produced only aflatoxin, and 14 produced only cyclopiazonic acid. Thirty-three percent of the strains of *A. flavus* were aflatoxigenic under the conditions used. Although the older literature contains references to other species even belonging to different genera producing aflatoxins, these have never been confirmed with the exception of a report[98] claiming to confirm an earlier observation that aflatoxins are produced by *Aspergillus ruber*.[92]

53.2.2 Occurrence

The aflatoxigenic molds occur in warmer parts of the world, and aflatoxins may be produced in a wide range of tropical and subtropical food commodities, such as figs, tree nuts, and cereals. The most important crops are corn and groundnuts, but it can also occur in temperate crops such as wheat.[166] Table 53–5 lists some of the more recent reports on the occurrence of aflatoxins in foods.

Although the aflatoxigenic species of *Aspergillus* cannot normally compete with the indigenous mold flora in temperate climates, viable spores occur in the atmosphere and on imported commodities in many parts of the world, and there have been occasions when aflatoxin production has occurred in British and Scandinavian barley. The storage of high-moisture cereals for nutritious winter feeds can be achieved by lactic fermentation or by adding acids such as ethanoic and propionic acids. The presence of 1% propionic acid completely inhibits the production of aflatoxin and ochratoxin in high-moisture cereals;[192] however, in both the United Kingdom (UK)[68] and Sweden,[140] aflatoxin was found in home-grown cereals inadequately treated with propionic acid. Indeed, it was shown subsequently that certain concentrations of propionic acid, which only partially inhibit growth of *A. flavus*, actually enhance the levels of aflatoxin produced.[3]

The complex ecology of these molds recently was reviewed by Cotty et al.[38] Although the production of aflatoxin initially was considered to be a problem in postharvest crops stored at inappropriate temperatures and water activities, it is now well appreciated that these compounds can be present in the field before harvest. *Aspergillus flavus* and *A. parasiticus* may infect healthy plants at a very early stage in their development and establish a benign endophytic relationship in crops such as corn and groundnuts. However, if the infected plant is stressed by such conditions as drought, then significant levels of aflatoxins may be produced in apparently healthy seed and are thus present postharvest, however good the subsequent storage conditions. This group of fungi also has an association with insects and insect damage of developing crops may also predispose them to infection and aflatoxin contamination.

Contamination of components of a crop, such as individual corn kernels or groundnuts, has a very skewed distribution; for example, the maize kernels on the same cob can be contaminated with a wide range of concentrations of aflatoxins, some having undetectable levels even though infected with *A. flavus*.[97] Individual cotton bolls on the same stem may have as little as 10 μg aflatoxin kg^{-1} or as much as 22,240 μg kg^{-1}, and again many of the bolls remain uncontaminated.[39] A detailed study of a large consignment of dried figs dramatically demonstrated the extremely skewed distribution of aflatoxin,[165] and an analysis of the distribution of aflatoxin in pistachios demonstrated that 90% of the aflatoxin was

Table 53–5 Recent Reports on the Occurrence of Aflatoxins in Foods

Commodity	*Country*	*Levels*	*Reference*
Groundnuts	India	21% >30 ppb	13

Corn	Brazil	12.3% 10 to 900 ppb	153
Corn	India	9–40% >20 ppb	168
Corn	Pakistan	48 × 500 g 21 to 385 ppb (distribution study)	81
Mustard seed	India	44% Tr to 750 ppb	154
Mustard cake	India	80% 100 to 1420 ppb	154
Mustard oil	India	33% 55 to 87 ppb	154
Dried figs	Turkey	4% mean 112 ppb	16
Herbs and spices	UK	6% >10 ppb	105
Spices	Egypt	4% 10 to 35 ppb	7
Meat products	Egypt	3.3% 6 to 175 ppb	7

present in 4.6% of the product, which was demonstrably of low quality.[158] This latter study demonstrated that it should be possible to reduce total aflatoxin in a product by identifying and rejecting the contaminated nuts. The significance of these studies is of considerable importance when establishing sampling plans for monitoring compliance with the legislative or advisory limits discussed below.

53.2.3 Biological Effects

The aflatoxins are acute hepatotoxins, and the four most frequently encountered members of the family vary in their toxicity to a single animal species (Table 53–6). Aflatoxins also are known to be carcinogenic in some animal species,[104] such as the rat and the rainbow trout. The presence of 100 μg kg^{-1} in a diet fed to rats for 54 to 88 weeks gave 100% incidence of tumors, and as little as 8 μg kg^{-1} in a diet fed to rainbow trout for a year gave 40% incidence of tumors. Liver cancer in rainbow trout became a problem when fish farms changed from animal protein to cottonseed meal as a source of protein in the pelleted feed. Rainbow trout are so sensitive that the etiology of this disease was unresolved until after the discovery of the aflatoxins following the outbreak of Turkey X disease in the UK in 1959 and the development of sufficiently sensitive and specific analytical methods. Carcinogenicity is species specific and no tumors were reported in mice fed on a diet containing as much as 150 μg aflatoxin kg^{-1} for 80 weeks. Thus there is considerable variation in both the acute and chronic toxicity of a single aflatoxin to a range of animal species and between the sexes and ages of the same species (Table 53–7). These observations would suggest that the toxicological effects of the aflatoxins are influenced by, or even dependent on, the metabolism of aflatoxin after intake into the body. This is now known to be the case.[124] The most important products of animal metabolism are shown in Figure 53–4. Aflatoxin B_1 epoxide certainly plays a central role in the toxicology of the aflatoxins,[71] and it has been shown to react very effectively and specifically with N^7 of guanine in DNA to form well-defined adducts. Aflatoxin B_1 is certainly acutely toxic to humans, is probably responsible for liver necrosis following chronic exposure, and may be involved in the epidemiology of human liver cancer in some parts of the world.

Table 53–6 Single Dose LD_{50} of Aflatoxins in Day-Old Ducklings

Aflatoxin	*LD_{50} (mg kg^{-1})*
B_1	0.36
B_2	1.9

G_2	3.5

Where hepatocellular carcinoma in humans is high, the presence of aflatoxin is accompanied by exposure to hepatitis B virus. Studies in Gambia supported a hypothesis that liver damage arising from hepatitis B infection may enhance the carcinogenic activity of aflatoxin.[198] However, detailed studies in Taiwan suggested that the role of aflatoxin in the epidemiology of liver cancer is not dependent on infection by hepatitis B virus.[74]

There are several parts of the world, especially in the tropical and subtropical areas of Africa, India, Southeast Asia, and Central and South America, where many people are exposed to foods contaminated with aflatoxin.[177] The toxicological response may be acute, as in the case of the outbreak of aflatoxicosis in India,[87] or chronic leading to liver damage and possibly eventually to primary hepatocellular carcinoma. The evidence for a strong statistical association between aflatoxin injestion and primary liver carcinoma is based on more than 25 years of epidemiological surveys in several parts of the world.[200] It is certain that the association of liver cancer and aflatoxin is complex and may involve synergistic interactions with other agents such as hepatitis B virus.[4,78,164,191] It has been shown that, not only does aflatoxin react with guanine residues in DNA after activation to the epoxide, but that there are very specific hot spots for such reactions.[75,102,183] Both hepatitis B virus and aflatoxin may enhance mutations of the p53 tumor suppressor gene;[77] thus each may contribute independently as well as acting synergistically to the incidence of hepatocellular carcinoma.

Table 53–7 LD_{50} Values for Aflatoxin B_1

Animal Species	*Oral LD_{50} (mg kg^{-1})*
Cat	0.55
Dog	0.5–1.0
Guinea pig	1.0–1.4
Hamster	10.2

Chicken	6.3
Pig	0.6
Rainbow trout	0.8
Sheep	1.0–2.0
Baboon	2.0
Macaque monkey	7.8

One aspect of the metabolism of aflatoxin, which is especially important in assessing and controlling human exposure, is the conversion of aflatoxin B_1 to its 4-hydroxy derivative, aflatoxin M_1 (Figure 53–4) in the cow[76] and its subsequent excretion in milk. The carryover of aflatoxin B_1 in feedstuffs as aflatoxin M_1 in milk is of the order of 1% to 2% but varies from animal to animal and day to day, being strongly influenced by the physiological status of the cow. The occurrence, toxicity, and regulation of aflatoxin M_1 have been thoroughly reviewed by Van Egmond.[188] Although it is similar in acute toxicity to aflatoxin B_1, the milk metabolite is significantly less carcinogenic in experimental animals.

This same metabolic transformation also occurs in humans, and an extensive study in the United Arab Emirates demonstrated the presence of aflatoxin M_1 in human milk and showed that many commonly used food ingredients, such as cereals, pulses, pistachios, Brazil nuts, walnuts, and almonds, contained aflatoxin B_1.[151,152]

There are now many reports of the occurrence of aflatoxins and aflatoxin derivatives in human blood, urine, and milk. Based on a detailed study in the Philippines during 1967–1969, Campbell et al.[22] demonstrated the presence of aflatoxin M_1 in the urine of children exposed to dietary aflatoxin B_1. The main source in this case was probably peanut butter, 29 samples of which had a mean concentration of 500 ppb. From these studies the authors suggested that aflatoxin M_1 could be detected in the urine of children if they were consuming in excess of 10 to 15 μg aflatoxin B_1 per day. Aflatoxin B_1 itself was not detected in the urine samples and the efficiency of conversion of dietary B_1 to urinary M_1 was only a few percent. This was confirmed in a study in Guangzxi Province, China, in which a mean daily intake of B_1 and mean daily excretion of M_1 were 66 and 0.7 μg per person per day respectively.[206]

Aflatoxin M_1 was detected in the breast milk of Sudanese mothers[40] and in the blood and urine of

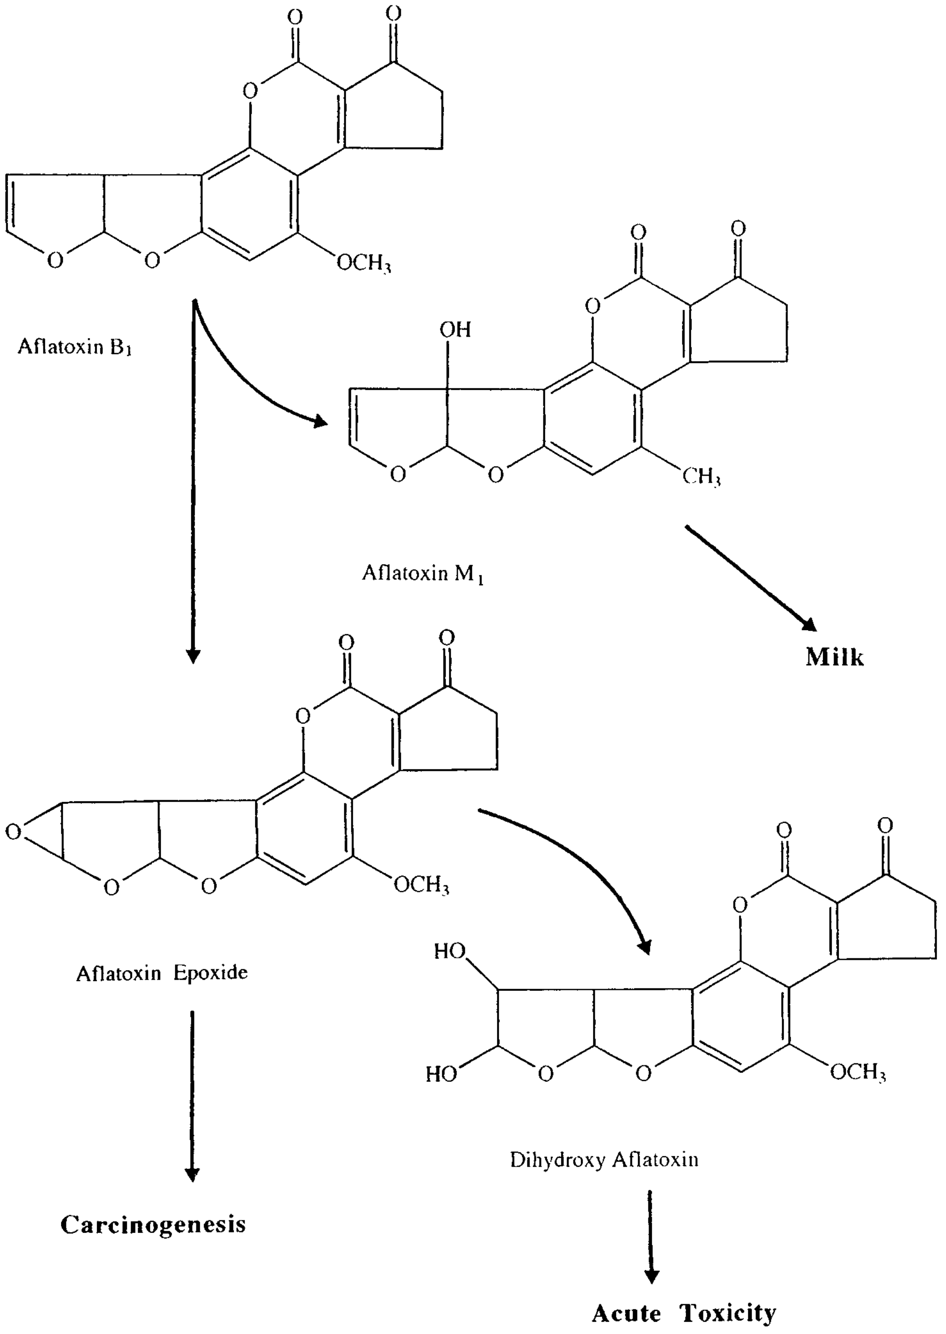

Figure 53–4 The Major Products of the Metabolism of Aflatoxin B_1 in the Liver.

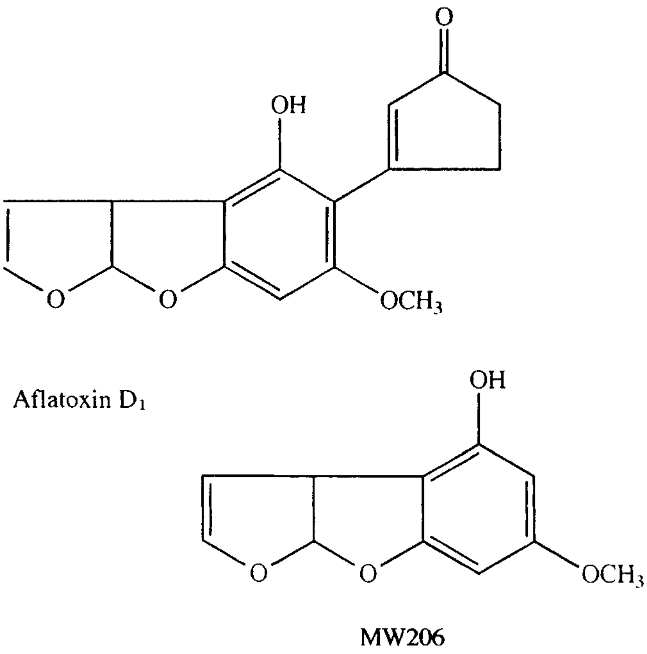
malnourished children in Sudan.[41] There are also reports of aflatoxin M_1 in human milk samples from rural villages in Zimbabwe[199] and Ghana.[95] As part of the latter study extended to Nigeria, venous blood from mothers and cord blood samples from infants were also studied, and aflatoxins were found in a significant number of these samples.

53.2.4 Control

Because aflatoxins are potentially widespread in occurrence and have an insidious combination of acute and chronic toxicity, it is prudent to control their presence in foods. Many countries have legislation establishing maximum tolerated levels,[189] which will be discussed later. Because there may be circumstances in which it is difficult to avoid contamination of large, economically valuable consignments of food and feed commodities with aflatoxins, a great deal of effort has been put into methods for decontamination using both physical[196] and chemical methods.[137] Although many chemical reagents have been tried, the most promising on a large scale is treatment with ammonia.[131] The major breakdown products from aflatoxin B_1 are aflatoxin D_1 and a compound having a molecular weight of 206 (Figure 53–5).

Although the initial opening of the δ-lactone ring is reversible, once this compound has undergone decarboxylation to aflatoxin D_1 and subsequent loss of the cyclopentenone ring to MW_{206}, the process is irreversible and the products are very much less toxic than aflatoxin B_1. One matter of concern was that degraded products from ammoniation of aflatoxin-contaminated commodities might be reconverted to active forms of aflatoxin in the acidic environment of the stomach. This has been shown not to be the case,[195] and a detailed inventory of the degradation of aflatoxin B_1 has been performed using ^{14}C-labeled material.[113] Reduction in levels of aflatoxin can be very dramatic; thus it has been shown that naturally contaminated cottonseed meal containing 4,000 ppb aflatoxins contained only 4 ppb after treatment for 30 minutes with 4% ammonia at 2.76 bar (40 psi) and 100° C.[130] In a detailed study in France, groundnut oil cake, contaminated with aflatoxins (1,000 ppb B_1 and 170 ppb G_1), was treated with ammonia gas for 15 min at 95° C at a pressure of either 2 or 3 bar. The two treatments led to a residual contamination of 140 ppb B_1 + 20 ppb G_1 and 60 ppb B_1 + 10 ppb G_1 respectively and were used in an 18-month feeding trial with rats.[54] It was reported that the percentage of hepatic tumors was high in animals fed untreated cake, fell sharply with the medium treatment, and was zero for the cake treated at 3 bar.



Aflatoxin D_1

MW206

Figure 53–5 Degradation Products of Aflatoxin B_1 Treated with Ammonia

For particulate commodities, such as nuts, in which it is known that the distribution of contamination is very skewed, it may be possible to use technologically sophisticated equipment to sort and discard the contaminated units. Such a system may involve an electro-optical sorter to remove fluorescent nuts when the fluorescence is known to be associated with aflatoxin contamination.[53]

It may also be possible to control the production of aflatoxin in the field by an integrated program of agricultural management that may include plant breeding, improved irrigation, and replacement of aflatoxigenic strains by non-aflatoxigenic strains of *A. flavus*.

53.3 THE OCHRATOXINS

53.3.1 Production

Ochratoxin A ($C_{20}H_{18}ClNO$) is a phenylalanyl derivative of a substituted isocoumarin (Figure 53–6), produced by *Penicillium verrucosum* in temperate climates and by several species of *Aspergillus* in warmer and tropical parts of the world. The most important species of *Aspergillus*-producing ochratoxin A is *A. ochraceus*; although *A. sclerotiorum*, *A. sulphureus*, and *A. melleus* also produce ochratoxin, they are rarely isolated from foods.

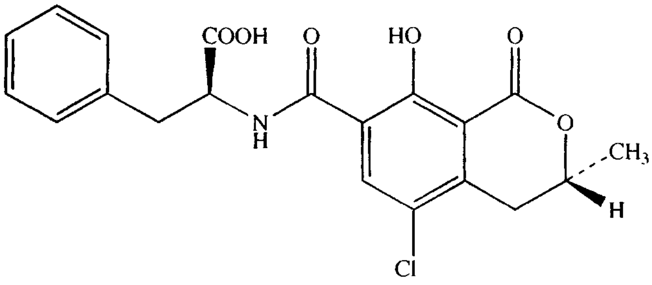


Figure 53–6 Ochratoxin A

Petromyces alliaceus, isolated from onions, is a good ochratoxin producer in the laboratory, and two species related to *A. niger*—*A. citricus* and *A. fonsecaeus*—have also recently been shown to produce ochratoxin, but their significance in foods is not yet known (Frisvad, personal communication).

Until relatively recently, ochratoxin A was considered to be produced by several species of *Penicillium*, such as *P. palitans*, *P. commune*, *P. variabile*, *P. purpurescens*, *P. cyclopium*, and *P. chrysogenum*, and *P. viridicatum* has been especially associated with this mycotoxin in the earlier literature. Ciegler et al.[34] studied 52 isolates of molds identified at that time as *P. viridicatum* and divided them into three groups on the basis of growth rate, colony morphology, odor, source, and ability to produce ochratoxin and/or citrinin. Group I (21 isolates) did not produce ochratoxin or citrinin and represent what is now accepted as the well-defined species *P. viridicatum*. Groups II (17 isolates) and III (13 isolates) included strains that produce either ochratoxin or citrinin or both and would now be referred to *P. verrucosum*.

In their detailed studies of secondary metabolite production by species of the terverticillate penicillia, Frisvad also demonstrated that strains previously referred to as *P. viridicatum* could be separated into a number of distinct chemotypes among which was a group producing ochratoxin A.[55] This group subsequently was shown to fit the description of *P. verrucossum*,[56,141] and it is now widely accepted that this is the only species of *Penicillium* producing ochratoxin A. There are also several unconfirmed but important reports of other species of *Aspergillus* and *Penicillium* producing ochratoxin.[29,103]

The different requirements of the two major ochratoxin-producing species are further illustrated by the influence of different plant commodities when used as the substrate for growth and ochratoxin production. Thus Madhyastha et al.[106] clearly showed that *Aspergillus ochraceus* (= *A. alutaceus*) produces more ochratoxins on groundnuts and soybeans than on corn and wheat, whereas the reverse was true for *P. verrucosum*. At an even more subtle level of substrate mold interaction, Häggblom and Ghosh[70] showed that the postharvest production of ochratoxin A by both *A. ochraceus* and *P. verrucosum* on barley was influenced by the level of nitrogen fertilizer applied to the growing crop. Fertilizer applications of 0, 90, or 240 kg ha^{-1} produced grain containing 9.1%, 10.4%, or 12.0% protein, respectively, and ochratoxin production increased with increasing protein content in a manner that could not be explained simply by the effects of the substrates on fungal growth.

The two major ochratoxin-producing molds differ in the conditions of temperature and water activity (a_w) that are optimum for growth and ochratoxin production.[8,128] Thus, the minimum a_w for growth of *P. verrucosum* is 0.81 and for *A. ochraceus*, 0.76, and at optimum a_w the temperature range for ochratoxin is 4° C to 31° C (opt 24° C) for *P. verrucosum* and 12° C to 37° C (opt 25° C) for *A. ochraceus*.

Biosynthetically, the isocoumarin structure of the ochratoxins is based on a pentaketide skeleton, to which a chlorine atom has been introduced and a C_1 unit has been added and subsequently oxidized to carboxyl. It is through this additional carboxyl group that L-phenylalanine is linked. This same pentaketide skeleton also can give rise to the mycotoxins austdiol (by the addition of two C_1 units) and citrinin (by the addition of three C_1 units), the C_1 units being derived from methionine.[119]

Like most mycotoxins, and other secondary metabolites, ochratoxin A is one of a family of compounds (Figure 53–6), but it is usually only ochratoxin A and occasionally the dechloro compound ochratoxin B that are found to occur naturally in moldy plant products. It is possible that ochratoxin C, the ethyl ester of ochratoxin A, is more widespread than presently recorded. Its toxicity is comparable to that of ochratoxin A, because it is readily de-esterified in the animal body, whereas the absence of the chlorine atom in ochratoxin B is associated with a considerable decrease in toxicity.

As already noted in the case of aflatoxin, the secondary metabolism of molds also may be influenced by the presence of inhibitory compounds such as agricultural biocides.[123] Ochratoxin biosynthesis is no exception and it has been shown, for example, that the presence of subinhibitory concentrations of phosphine may increase levels of ochratoxin produced.[193] On the other hand, dichlorvos inhibit ochratoxin biosynthesis at concentrations that have relatively little effect on growth.[201] Ionizing radiation, at levels that damage spores but do not kill them, may lead to enhanced levels of ochratoxin production,[5,134] but the significance of these observations for irradiated foods has still to be critically assessed.

53.3.2 Occurrence

P. verrucosum is especially associated with stored cereals, although it has also been isolated from meat and fish;[127] however, the occurrence of ochratoxin A in meat products is usually due to transmission into muscle, kidney, and blood in animals fed on contaminated animal feed such as barley. Ochratoxin A may also be transferred from dietary intake into milk because it has been detected in both cow's milk and human milk.[18] This is the second example of a mycotoxin that can be passed through the food chain and appear in a commodity that has not been molded. *A. ochraceus*, on the other hand, is common on coffee beans and spices and also is isolated from cocoa beans, soybeans, groundnuts, rice, and corn.[91] Krogh[90] has provided an extensive list and bibliography of foods and feeds of plant origin in which ochratoxin A has been found to occur naturally, and reports of its occurrence in food commodities continue to appear (Table 53–8). The demonstration that ochratoxin is not destroyed by roasting of naturally contaminated coffee beans[178,185] has led to an increase in the surveillance of this particular commodity and the demonstration of a persistent but low level of contamination (Table 53–9). Earlier reports of degradation during roasting often were based on materials spiked with pure toxin, and this superficial contamination is rather easily removed with the outer layers of the coffee beans during the roasting process.

53.3.3 Biological Activity

Ochratoxin has been known for some time to be a major etiological agent in porcine nephropathy,[88] and by analogy it has been considered to be associated with the chronic progressive kidney disease in humans known as Balkan endemic nephropathy.[24] Nearly 20 years ago, there were suggestions that the human disorder may involve mycotoxins other than ochratoxin,[9] and more recently Mantle et al.[111] have provided convincing evidence that toxic metabolites of penicillia that do not produce ochratoxin may be important in Balkan nephropathy. Nevertheless, concern about ochratoxin A has been highlighted by the increasing evidence that it should be considered as a carcinogen with genotoxic properties as well as being a potent nephrotoxin. The availability of improved methods of analysis has demonstrated that ochratoxin is quite widespread in foods, and its presence in human body fluids confirms that there is a significant exposure within the human population.[18]

Ochratoxin A is immunosuppressive[96] and inhibits protein biosynthesis. It almost certainly has a number of interacting effects on target organs, but at the molecular level it is known to inhibit the

Table 53–8 Reports of the Occurrence of Ochratoxin in Foods

Commodity	*Country*	*Levels*	*Reference*
Corn	France	2% 15 to 200 ppb	59
Corn	Yugoslavia	8.3% 6 to 140 ppb	136
Corn	UK	13% 1 to 11.2 ppb	108
Wheat	Yugoslavia	8.2% 14 to 135 ppb	136
Wheat	Denmark	29% 0.05 to 51 ppb	84
Wheat	Czechoslovakia	12% >20 ppb	57
Barley	Yugoslavia	12.5% 14 to 27 ppb	136
Barley	Denmark	27% 0.05 to 5.6 ppb	84
Barley	Czechoslovakia	6% >20 ppb	57
Barley	UK	17% 1 to 45 ppb	108
Soya	UK	26% 50 to 500 ppb	107
Cocoa beans (raw)	UK	18% 100 to 500 ppb	107
Cocoa (roasted)	UK	16% 100 ppb	107
Herbal drugs	India	40% 0.07 to 2.3 ppm	150
Pig kidney	UK	15% 1 to 9.3 ppb	108
Black pudding	UK	13% 1 to 1.8 ppb	108

Green (decaf.)	6/17 (35)	0.26 to 7.7	110

phenylalanyl transfer RNA synthetase enzyme involved in protein biosynthesis. It is thus natural to ask whether other amino acid analogs would have analogous effects. A number of other analogs have been synthesized and shown to be active to some extent in *in vitro* tests with monkey kidney epithelial cells.[174] Creppy et al.[43] used eight such analogs in a cell-free system based on the appropriate purified tRNA synthetases from a yeast and demonstrated that they all had some inhibitory activity but that it varied with the amino acid. Ochratoxin A itself (the phenylalanyl derivative) was the most active, and the tyrosinyl, valyl, seryl, and alanyl derivatives were very active, but the prolyl derivative was the least active. Several natural analogs of ochratoxin A have been shown to occur in cultures of *Aspergillus ochraceus*, in which the phenylalanyl side chain is replaced with either serine, hydroxyproline, or lysine,[69] and further analogs of ochratoxin A have been chemically synthesized for the study of metabolic and immunological structure/activity relationships.[202]

Ochratoxin A has been classified by the International Agency for Research on Cancer (IARC) as a possible human carcinogen.[79] There is no doubt that doses as low as 70 μg kg^{-1} body weight can induce kidney tumors in male rats. The male rat is about 10 times more sensitive than the female rat and about 100 times more sensitive than the male mouse to the carcinogenicity of ochratoxin A. These observations do not in themselves help us assess whether ochratoxin is carcinogenic to humans, but it is prudent to maintain vigilance until it is confirmed that it is not. Many tests for genotoxicity have proved to be negative but the occurrence of single-strand breaks in DNA in a number of tissues in mice exposed to ochratoxin A have been demonstrated.[42] Evidence for the role of metabolic activation involving cytochrome P450 in the mutagenicity and genotoxicity of ochratoxin A also has been presented;[47] and this article should be consulted for a discussion of the recent literature on this subject. Risk assessments of ochratoxin A have led to recommendations of provisional tolerable daily intakes of between 5 and 16 ng kg^{-1} body weight (bw) per day. There are two ways of estimating exposure: analysis of components of diet or analysis of body fluids, such as blood. Both of these methods have been used in a number of European countries that are in reasonable agreement, suggesting mean exposures of the order of 1 to 2 ng kg^{-1} bw per day, the greatest exposure being from cereals and cereal products and only about 0.06 ng kg^{-1} bw per day from coffee and coffee products.

53.3.4 Control

Once ochratoxin A has been formed in a food, it would seem likely that it would be difficult to remove by most forms of food processing. The ability to survive the coffee roasting process has already been discussed above and it has been shown more recently that, even at temperatures as high as 250° C, complete destruction of ochratoxin A was not achieved.[15] The calculated half-lives for ochratoxin A in dry wheat were 707, 201, 12, and 6 minutes at 100° C, 150° C, 200° C, and 250° C, respectively, and in wet wheat the corresponding figures were 145, 60, and 19 minutes at 100° C, 150° C, and 200° C. Cooking, with or without previous soaking, removed a significant amount of ochratoxin from beans but did not lead to total destruction. Beans still contained 16% to 60% of the initial ochratoxin contamination and it seems probable that the material removed was leached out of the beans rather than destroyed.

53.4 PATULIN

53.4.1 Production

Patulin (Figure 53–7) is a toxic and antibiotic metabolite produced by several species of molds in the genera *Penicillium*, *Aspergillus*, and *Paecilomyces*, but the most important in the context of human food production is *Penicillium expansum*, a soft rot pathogen of apples and pears. *Aspergillus clavatus* commonly is associated with malted barley residues used in animal feeds and was implicated in an outbreak of patulin poisoning of cattle that grazed on barley stubble. Moreau provides a detailed account of the role of this species in outbreaks of poisoning of cattle fed on barley malt and cereal sprouts.[118] *Paecilomyces*, the imperfect stage of *Byssochlamys*, may contaminate silage and is implicated in the occasional problem with patulin contamination in silage. Because patulin first was isolated independently by several groups as a potentially useful wide-spectrum antibiotic, it has been known under several different names: clavacin, clavatin, claviformin, expansin, leucopin, mycoin C, penicidin, and tercinin. Indeed, it underwent quite extensive trials as an antibiotic before being abandoned on toxicological grounds.

Patulin proved to be a very useful model for studies of the biosynthesis of polyketide secondary metabolites, being essentially an extensively rearranged tetraketide,[205] but current interest in this molecule arises because of the toxicological significance of its presence in foods.

53.4.2 Occurrence

Possibly the first report of *Penicillium expansum* producing patulin in apples was that of Brian, Elson, and Lowe,[19] and the first report of its natural occurrence in apple juice was that of Scott et al.[162] Since then, it has been found in a range of foods based on fruits from many countries in concentrations ranging from 1 to 250,000 μg kg^{-1}.[145] Concern over patulin in the UK was expressed when a survey of samples of apple juices in 1992 demonstrated the presence of unexpectedly high concentration in 4 of 32 samples.[108] In the same year, an Australian survey showed that 57.5% of fruit juices tested contained patulin, 28% of which exceeded 50 μg l^{-1}.[20] The presence of patulin in a fruit juice is a useful indicator that the juice was expressed from poor quality fruit, which is undesirable and should be avoidable with good manufacturing practice; however, increasingly detailed studies of the occurrence of patulin in apples has demonstrated that it may occur in what looks like sound fruit. This is particularly a problem with those varieties that have an open core structure, such as Bramleys, in which mold growth can occur in the core. The presence of patulin in apple juice usually would arise from contaminated apples but, in the laboratory, *P. expansum* can produce patulin when growing in apple juice. In this situation, it has been shown that there may be quite a narrow pH range (3.2 to 3.8) for optimum patulin production.[46]

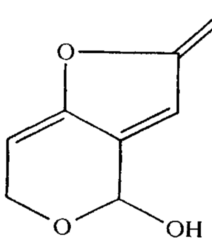

Figure 53–7 Patulin

53.4.3 Biological Activity

Patulin has an acute oral LD_{50} in rodents of about 30 to 50 mg kg^{-1} [197] and has been shown to be teratogenic, immunotoxic, and neurotoxic and to cause gastrointestinal disturbances in rats. Patulin is quite rapidly excreted from an animal, and a single dose of ^{14}C-labeled patulin was excreted in the feces (49%), urine (36%), and as $^{14}CO_2$ in expired air (1% to 2%) within 7 days.[45]

A review of the toxicology of patulin has made it prudent to regard it as a mutagen, although none of the Ames type of assays were positive in the pres-

Next Page

ence or absence of exogenous activating systems. The evidence for carcinogenicity still is equivocal; however, because of all these observations, and an increased popularity of apple juice, an advisory level of 50 µg l^{-1} has been established in the UK, and a survey carried out in 1993 showed that only 3 of 62 samples exceeded that level and none of these were in excess of 100 µg l^{-1}. A further survey reported in 1995[109] showed no detectable levels of patulin in any of 128 samples of fruit juice or 26 samples of tomato products.

53.4.4 Control

In apples molded by *Penicillium expansum*, most of the patulin is confined to the region of damaged tissue, and simply removing the lesion reduces the toxin by 90%, but if 1 cm around the lesion is also removed, no patulin is detectable in the rest of the apple.[181]

Although stable in some aqueous environments at low pH, patulin is chemically reactive, and it has been known for some time that it disappears during a yeast fermentation.[175,176] Patulin has wide-spectrum antibiotic activity and it has been demonstrated that up to 50 mg l^{-1} (a concentration far in excess of any likely to be found in apple juice!) may only cause transient inhibition of *Saccharomyces cerevisiae* while the organism is degrading the patulin.[17,73,182] It also has been shown that the degradation of patulin by yeast depends on protein synthesis and that the toxin is not degraded when added simultaneously with the protein synthesis inhibitor cycloheximide.[179]

Although it is probable that the degradation of patulin during a yeast fermentation in, for example, the manufacture of cider leads to loss of toxicity, it would still be useful to understand the nature of this degradation. Characterization of a degradation product could provide an indicator that cider was manufactured from poor quality apple juice in the same way that patulin itself is an indicator that a juice was manufactured from poor quality apples. Patulin reacts with free sulphydryl groups and with sulphur dioxide to give products that seem no longer to be toxic. Ascorbic acid also has been reported to reduce levels of patulin, but it is not yet clear what the breakdown products are. Although pasteurization (using high-temperature, short-time treatment of 10 seconds at 90° C) causes some reduction in patulin in fruit juices, it is only of the order of 20%, which is not sufficient to make a badly contaminated product acceptable.[72]

53.5 THE *FUSARIUM* TOXINS

Another important genus of mycotoxin producers is *Fusarium*, many species of which produce members of the trichothecene family of mold metabolites. Identification of species of *Fusarium* is not always straightforward, and several trichothecenes have been named after species of *Fusarium* now known not to produce them.[112] Thus nivalenol was thought to be produced by *F. nivale* (no longer considered to be a species of *Fusarium* but referred to *Monographella nivalis*!) and neosolaniol was thought to be produced by *F. solani*. Although fortunately not frequently found in foods, one of the most toxic of the *Fusarium* trichothecenes is T-2 toxin (Figure 53–2). This toxin is thought to have contributed to the epidemiology of the terrible outbreaks of ATA in Russia. In these instances, it was produced by species such as *Fusarium sporotrichioides* and *F. poae* growing on overwintered cereals. The trichothecenes are acutely cytotoxic and strongly immunosuppressive and, indeed, many of the deaths occurring during outbreaks of ATA were recorded as due to relatively trivial pulmonary infections of viruses and bacteria.

53.5.1 Deoxynivalenol

Deoxynivalenol (DON) (Figure 53–8) is a far more common, but much less toxic, trichothecene and is produced by species such as *F. graminearum* and *F. culmorum*, both of which also produce the estrogenic mycotoxin zearalenone (Figure 53–9). Although the LD_{50} of T-2 toxin is about 5 mg kg^{-1} in a wide range of animal species, that of DON is about 70 mg kg^{-1} in the mouse. An earlier name for DON was vomitoxin because it elicits a vomiting response in pigs at doses as low as 0.1 mg kg^{-1} bw and, indeed, is quite a potent feed refusal factor. Reports on the

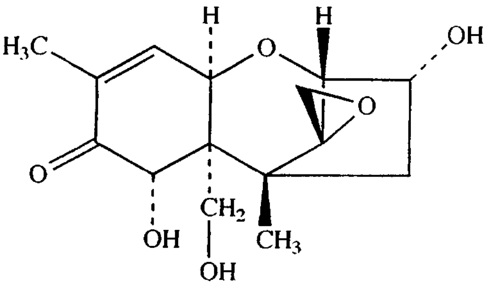

Figure 53–8 Deoxynivalenol

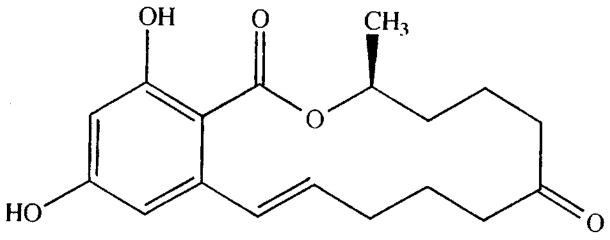

Figure 53–9 Zearalenone

occurrence of deoxynivalenol are shown in Table 53–10. The problem with assessing the significance of deoxynivalenol in foods is the frequent cocontamination with acetylated derivatives such as 3- and 15-acetyl-deoxynivalenol. The production of these two particular derivatives has been used to distinguish chemotypes of *F. graminearum* with interesting geographical distributions. Thus 3-acetyl-DON is associated with the Far East while 15-acetyl-DON is associated with strains from the US.[116] The first demonstration of 15-acetyl-DON in US corn implicated in feed refusal by pigs was considered to possibly "account in part for the refusal that could not be solely attributed to deoxynivalenol."[1]

The trichothecenes are remarkably stable compounds, and DON will survive both dry milling and wet milling processes of corn,[64] the experimental milling of wheat from which 76% is retained in the straight-grade flour.[160] The baking of bread has relatively little effect on trichothecenes such as DON.[51,85]

Table 53–10 Reports on the Occurrence of Deoxynivalenol and Related Toxins (ie, type B Trichothecenes)

Commodity	*Country*	*Levels*	*Reference*
Corn (moldy)	Italy	18 to 668 ppb	14
Corn (moldy)	US	mean 238 ppb	132
Barley	Korea	29 to 677 ppb	133
Barley	Japan	86 to 70,500 ppb	203
Wheat	USSR	100 to 1,390 ppb	187
Wheat	Japan	29 to 11,700 ppb	203
Wheat	Poland	9.6 to 25.3 ppm	138

53.5.2 Zearalenone

Zearalenone, which was first isolated as the agent responsible for vulvovaginitis in pigs, has very little acute toxicity, but there should be some concern about chronic exposure to a compound known to be estrogenic. It may be produced, together with DON and other trichothecenes, in a wide range of cereals including corn, barley, and wheat. A few examples of the occurrence of zearalenone are shown in Table 53–11. As well as estrogenic activity, zearalenone and its derivatives have anabolic, growth promoting activity. Both α-zearalanol (= zeranol) and α-zearalenol (marketed under the tradename Ralgro[170]) have increased anabolic activity compared with zearalenone itself and are used as animal feed additives in some parts of the world. Both these compounds are themselves natural products of species of *Fusarium*[12] and zearalenol is produced by the metabolism of zearalenone in the animal body.

53.5.3 Moniliformin

Moniliformin first was obtained from a strain of *Fusarium moniliforme* isolated from southern leaf blight-damaged corn seed as a water soluble toxin with an oral LD_{50} of 4.0 mg kg^{-1} in 1-day-old cockerels.[36] It also has potent phytotoxic activity. The remarkable structure (Figure 53–10) of this cyclobutane derivative was confirmed by single crystal x-ray crystallography and chemical synthesis of the potassium salt.[172] *F. moniliforme* is not a major producer of this toxin, but many other species of *Fusarium* produce it with, perhaps, *F. subglutinans*, *F. acuminatum*, and *F. avenaceum* being major producers.[30] Moniliformin can be quite a common contaminant of cereals and it was found in samples of Polish corn every year during a survey from 1985 to 1991 with levels ranging from 4.2 to 530 ppm.[101] A survey of 36 samples of retail corn products in the

Table 53–11 Reports on the Occurrence of Zearalenone

Commodity	*Country*	*Levels*	*Reference*
Corn (moldy)	Italy	156 to 7433 ppb	14
Corn (moldy)	USA	mean 904 ppb	132
Barley	Korea	40 to 1,416 ppb	133
Barley	Japan	105 to 15,300 ppb	203
Wheat	Japan	53 to 459 ppb	203
Wheat (moldy)	Poland	mean 0.29 ppm	139

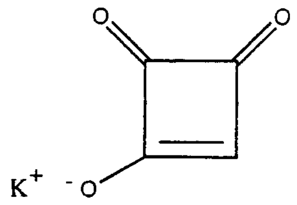

Figure 53–10 Moniliformin

UK during 1990 showed most samples to contain low but measurable levels of about 100 ppb with a maximum of 250 ppb in a single sample of cornmeal.[108] A further 55 samples of corn from Africa, Asia, and continental Europe also were analyzed during this survey. Although 30 of these samples contained no detectable moniliformin, a sample from the Gambia contained 3,160 ppb.

The LD_{50} for mice has been reported to be 20.9 mg kg^{-1} for females and 29.1 mg kg^{-1} for males. At toxic doses moniliformin causes rapid death without obvious overt cellular damage; although acute degenerative lesions in the myocardium are reported. This is particularly interesting because of the possible link between moniliformin and a human disorder known as Keshan disease seen in parts of China.[32] Members of the Liseola group of fusaria, including *F. moniliforme* and *F. subglutinans*, have been known to be very toxigenic despite not producing trichothecenes. They have been associated with esophageal carcinoma in humans, but the toxicology of pure moniliformin does not account for the observed biological effects of these organisms. The highly toxic and mutagenic metabolite fusarin C (Figure 53–11) seemed a good candidate,[65] but this also does not account for the carcinogenicity and other biological effects associated with culture filtrates of strains of *F. moniliforme*. The remarkable diversity of secondary metabolites of this group of fusaria was further demonstrated by the more recent isolation and characterization of the fumonisins.

53.5.4 Fumonisins

The most recently characterized mycotoxins of any major significance in human health are the fumonisins produced by species of *Fusarium*, such as *F. moniliforme*, which are known not to produce the trichothecenes.[60] Recent studies have shown that fumonisin production is variable within the different mating types of the perfect state of *F. moniliforme* (*Gibberella fujikuroi*)[99] and that it may be produced by quite a large number of species of *Fusarium*.[125] The genetic variability in the production of the fumonisins and fusarins also has been demonstrated with isolates of *F. moniliforme* from Indonesia, the Philippines, and Thailand.[117] Indeed, it has been shown to be produced by the unrelated mold *Alternaria alternata*.[31]

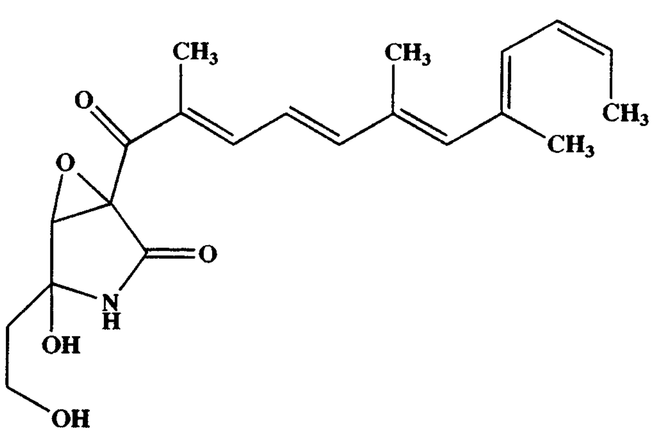

Figure 53–11 Fusarin C

Fumonisin B_1 (Figure 53–12) is water soluble, has considerable biological activity, is known to be responsible for equine encephalomalacia, porcine pulmonary edema syndrome, and hepatic cancer in rats, and may be involved in the epidemiology of esophageal carcinoma in humans in southern Africa[147] and parts of China, although, in the latter case, the correlation is not so convincing.[204] Now that methods for its analysis have become more widely available, it appears to be quite common in corn and corn products in Italy,[49] Portugal, Zambia, and Benin.[48] Indeed, Sydenham et al.[180] describe methods for the partial decontamination of bulk shipments of corn and also provide a useful bibliography of the occurrence and analysis of the fumonisins. Like a number of mycotoxins, the fumonisins are relatively heat stable and would not be significantly destroyed by drying processes for corn or heat treatments used for the production of maize derivatives.[50]

53.6 ANALYSIS

The diversity of chemical structure of mycotoxins, and the wide range of foods and animal feeds in which some of them may occur, usually need the development of different analytical methods for each mycotoxin in each food commodity. Interna-

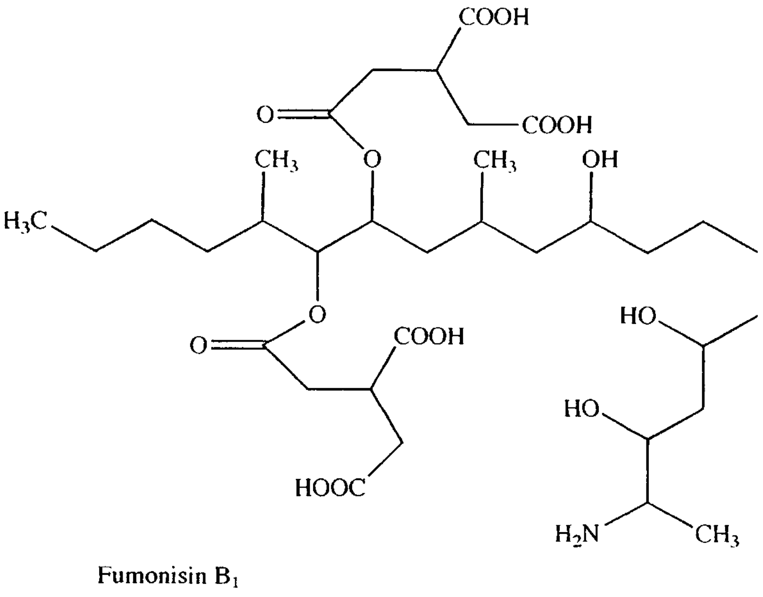

Figure 53–12 Fumonisin B_1

tional trade in many of the commodities most at risk from contamination requires the establishment of agreed methods of analysis, and many countries use those described in the Official Methods of Analysis of the Association of Official Analytical Chemists.[159]

53.6.1 Sampling

Before an analysis can be attempted, a sample must be obtained. The analyst frequently is presented with a single sample adequate in quantity for the analytical methodology, but without any guarantee that it is representative of the consignment from which it came. Many commodities to be analyzed are particulate in structure, and molds do not grow uniformly through such materials. Thus mycotoxins may not be distributed evenly throughout a consignment, although exceptions may be aflatoxins in milk and patulin in fruit juice. There is not even a normal distribution of mycotoxins within a batch of a commodity. For example, in the contamination of groundnuts, corn, cottonseed, or palm kernels with aflatoxin, it is likely that a relatively small number of kernels or seeds are contaminated with very high levels and many are not contaminated at all, giving a very skewed distribution.[82]

It is important to agree on a sampling plan that adequately protects the consumer without unnecessarily penalizing the producer. Satisfactory sampling plans, such as those devised for groundnuts by the US Department of Agriculture and the Tropical Products Institute (now the Natural Resources Institute) of the UK, define the size of the sample, how it is to be collected, a method for dividing the sample, and an analytical procedure. For many years sampling was not taken sufficiently seriously, but detailed research on the distribution of mycotoxins in commodities and an appropriate statistical analysis of the results have led to the increased use of acceptable sampling plans. The recognition of the extremely skewed distribution of mycotoxins has also led to the design of methods for spotting and eliminating the heavily contaminated kernels from consignments, thus ensuring that they do not contribute to the overall contamination of the batch after further treatment such as mixing, grinding, and oil extraction.

53.6.2 Extraction Procedures and Cleanup

Mycotoxins are produced in a complex matrix of macromolecules, including proteins, polysaccharides, and lipids, as well as being mixed with a range of low molecular-weight organic compounds of biological origin. Although many mycotoxins are readily soluble in water-immiscible organic solvents, it is not always easy to remove them from the macromolecular food matrix by direct extraction with simple solvents such as chloroform or ethyl acetate. It may be necessary to remove oils and fats by a preliminary extraction with hexane before extracting the mycotoxin. In the case of aflatoxin, detailed methods will vary from one commodity to another. Thus, defatted hazel nuts, pistachios, Brazil nuts, groundnuts, or groundnut meal can be extracted directly with chloroform after the addition of a small volume of water, whereas cottonseed and cottonseed products are best extracted initially with aqueous acetone and the aflatoxins subsequently partitioned into chloroform.

Those mycotoxins, such as ochratoxin A, that contain a carboxyl group can be extracted readily into chloroform after acidifying the commodity with aqueous phosphoric acid (0.1 M). Ochratoxin A can then be back-extracted from the chloroform using sodium bicarbonate solution or trapped on a column of diatomaceous earth impregnated with an aqueous solution of sodium bicarbonate. Esters and fat can be removed with hexane and chloroform and the acidic ochratoxin A eluted with a formic acid/chloroform mixture. It is worth noting that this method would miss ochratoxin C.

Some mycotoxins are sufficiently hydrophilic that they cannot be recovered efficiently with a simple chloroform extraction even though they are intrinsically soluble in chloroform. Among the trichothecenes, deoxynivalenol is best extracted initially with aqueous methanol, before subsequently partitioning into chloroform, and the fumonisins may be extracted from corn by soaking in distilled water for 2 to 3 hours with thorough mixing at intervals of about 30 minutes, or with methanol/water (80:20) for 30 minutes.

Cleanup procedures vary considerably depending on both the mycotoxin(s) and the commodity to be analyzed. A range of commercially available prepared columns, such as Sep-Pak, have proved very convenient as a cleanup stage for crude extracts of mycotoxins before subsequent analysis. The recovery of mycotoxins from all extraction and cleanup procedures needs to be validated; this may be done using spiked material prepared from clean samples of the commodity under study. It must, however, be recognized that it is usually easier to recover compounds from spiked samples than it is to recover the same mycotoxins from naturally contaminated material. For some mycotoxins, there are now samples available of naturally contaminated material, the mycotoxin content of which has been established by international collaborative studies.[62,63,190] The extraction and cleanup procedures usually will still provide a complex mixture requiring further separation before a specific physico-chemical method for the quantitative or qualitative analysis of individual mycotoxins can be applied. This further separation usually is carried out by some form of chromatography.

53.6.3 Chromatographic Methods

The most widely used technique is thin layer chromatography (TLC), in either one- or two-dimensional mode, but as they become more widely available, high-performance liquid chromatography (HPLC) and gas chromatography (GC) also have important roles in the analysis of mycotoxins.[35] A major advantage of HPLC is the possibility of automation, the use of autosamplers, and the possibilities of online cleanup of crude extracts and online derivatization before or after separation. There are well-established methods for the HPLC analysis of all the aflatoxins, zearalenone, the 8-keto trichothecenes, patulin (although resolution from 5-hydroxy methylfurfural can be a problem), and, most recently, for the fumonisins as their naphthalene 2,3-dicarboxyaldehyde derivatives.

For GC, the mycotoxins need to be sufficiently thermostable and volatile or be converted into volatile derivatives. The two most widely used detectors in mycotoxin analysis—flame ionization (FID) and electron capture (ECD)—do not require that a compound show any fluorescence or ultraviolet absorption, and the group of mycotoxins for which GC was initially the most suited were the trichothecenes, There is a large number of different trichothecenes, and ideally their analysis requires confirmation using mass spectroscopy coupled gas chromatography (GC-MS).[114] Capillary GC-MS offers such a sensitive tool now that nivalenol has been detected in samples of beer at concentrations as low as 0.1–0.84 ng ml^{-1}.[161] Recently the mass spectrometer has been applied as a sensitive confirmatory detector to HPLC for the detection of sterigmatocystin in cheese, bread, and corn products.[163]

53.6.4 Immunological Methods

Most of the traditional methods of mycotoxin analysis based on physico-chemical determination require the attention of a skilled analyst who would be hard pressed to complete the analysis of quite a small number of samples during a working day. The meaningful survey for the occurrence of mycotoxins in a commodity, or the routine monitoring of foods for the presence of mycotoxins, ideally requires the analysis of large numbers of samples and a number of biological assays,[148,149] and immunological approaches could make this possible.[33] Although mycotoxins are relatively small molecules, and hence not themselves immunologically active, they can form the haptens of an antigen by coupling to a suitable macromolecule such as bovine serum albumin. They may then present suitable epitopes to which specific antibodies can be raised. During the last few years, immunological methods have been developed for a wide range of mycotoxins including the aflatoxins, T-2 toxin, zearalenone, ochratoxin, cyclopiazonic acid, and, most recently, fumonisins B_1, B_2, and B_3.[6,52]

The specificity of monoclonal antibodies makes it possible to develop an analytical method for a single mycotoxin, such as aflatoxin B_1 in corn and groundnut meal or aflatoxin M_1 in milk and milk products. Even within chemically closely related structures such as the *Fusarium* trichothecenes, there is very little cross reactivity between a monoclonal raised to a single toxin such as T-2 toxin and other members of the family.[67] Both enzyme-linked immunosorbent assays (ELISA) and immuno-affinity columns are commercially available for a number of mycotoxins. ELISA is subject to interference from components in foods that may result in false positives,[94] but immunoaffinity columns are particularly useful as a very specific extraction, cleanup, and concentration stage in preparation for subsequent quantitative chromatographic analysis.

53.6.5 Safety Procedures

Mycotoxins should be handled as toxic substances and special care should be taken when handling pure toxins in a dry form or samples (including thin layer chromatography plates), which may be a source of dust. Accidental spillages of material containing aflatoxin generally can be treated with 1% sodium hypochlorite bleach, left for 10 minutes, swabbed down with 5% aqueous acetone initially, and subsequently rinsed with plenty of water.

Glassware exposed to aflatoxins can be rinsed with methanol, soaked in 1% NaOCl solution to which, after 2 hours, acetone is added to 5% of the total volume. The acetone is left for 30 minutes to destroy any potentially harmful but reactive intermediates formed by hypochlorite and then washed thoroughly. It is known, for example, that aflatoxin B_1 can form a carcinogenic derivative if treated with hypochlorite alone.

A detailed discussion of the laboratory decontamination and destruction of aflatoxins in laboratory wastes has been prepared for the IARC.[25]

53.7 SIGNIFICANCE AND LEGISLATION

The study of mycotoxins initially was concerned with isolated human illnesses, such as ATA, yellow rice disease, ergotism, and of the epidemiology of a number of illnesses in farm animals that could not be associated with such agents as infectious microorganisms, plant poisons, pesticide residues, or heavy metal poisoning. It gradually became apparent that molded animal feeds, or fungal infected forage in the field, could be responsible for illnesses such as sheep facial eczema, red clover disease, vulvovaginitis in pigs, feed refusal, turkey X disease, hepatocarcinoma in rainbow trout, and liver cancer in dogs. That these same compounds could be present in human foods, and possibly responsible for illness, only was appreciated when analytical methods made it possible to screen large numbers of foods and food components. There is no doubt that in tropical, developing countries, mycotoxins are responsible for acute illness and even the death of people although, even in these parts of the world, the numbers of people involved may be small compared with those who are ill and die from infectious diseases caused by protozoa, viruses, and bacteria.

In industrialized countries with a temperate climate, such as those of Northern Europe, it is difficult to assess the impact of mycotoxins on human health, although it is clear that they may have a political and economic impact. Thus the newspaper headlines "apple juice in cancer scare" was as much about the perception that there had been a coverup involving government as it was about knowledge of the occurrence and toxicity of patulin in apple juice. It was based on the finding that, of 32 samples of commercial apple juice analyzed, 5 had levels of patulin in excess of the advisory limit of 50 $\mu g\ kg^{-1}$ (they were 59, 82, 118, 153, and 434 $\mu g\ kg^{-1}$).[108] The presence of patulin in fresh apple juice implies the use of moldy fruit for its preparation; this is clearly undesirable. However, as we have already seen, the ecology of molds and their plant hosts, such as *Penicillium expansum* and apples, *Aspergillus flavus* and corn, and *Aspergillus parasiticus* and groundnuts, is more complex than postharvest molding of poorly stored commodities. These fungi may have a benign endophytic relationship with apparently healthy plants and low levels of mycotoxins may be produced as a result of stress, such as that caused by drought, of the crop during its development in the field. Because of this, there may be years when there is a detectable concentration of a mycotoxin in a crop even before it is harvested. Although there is no evidence at the moment that this is the case with patulin in apples, it has certainly happened with aflatoxins in corn and groundnuts. In 1980, the cost of aflatoxin contamination of corn in the South Eastern US arising in this manner was estimated at more than $237 million.[126] Because it would seem difficult to avoid contamination by aflatoxin in some commodities, attempts have been made to estimate the average daily intake for an adult in the US. The results suggest a level of 20 ng kg^{-1} bw for aflatoxin B_1, mainly from corn and corn products, and 0.8 ng kg^{-1} bw for aflatoxin M_1 from milk and milk products. It should be noted in this context that aflatoxin M_1 is less than one hundredth (1/100) times as carcinogenic as aflatoxin B_1.

Many countries have set legislative or recommended limits to the concentrations of a number of mycotoxins in foods (Table 53–12) and these may reflect analytical capability rather than a clear understanding of the toxicological significance or distribution of mycotoxins in foods. The inclusion of stachyobotriotoxin in animal feeds by Romania and phomopsin in lupin products by Australia reflect specific problems with these mycotoxins in those particular countries. Even for a single mycotoxin, such as aflatoxin, there is a wide range of maximum acceptable limits in different countries (Table 53–13). One of the major problems in setting legislative limits that will be acceptable to both the consumer and the producer is understanding the distribution of a mycotoxin in a bulk commodity, especially if it is particulate. Molds rarely grow uniformly throughout a commodity, and a mycotoxin will not have an even distribution. The study by Sharman et al.[165] showed that the batch average aflatoxin content for an 11-ton consignment of whole dried figs was 33 μg kg^{-1}, based on a single homogenized 20 kg sample made up of 20 × 1 kg subsamples. However, 67% of 200 boxes, each containing 12 kg and chosen at random from the 850 boxes making up the total consignment, had less than 10 μg kg^{-1}. Studies such as these demonstrate the need for accepted sampling plans to be incorporated into the analytical methodology and a number of such plans have been established.

Table 53–12 The Range of Regulatory Limits for Mycotoxins[144,189]

Mycotoxin	*Regulatory Limit (μg kg^{-1})*	*Number of Countries*
Aflatoxins in foods	0 to 50	53
Aflatoxin M_1 in milk	0 to 0.5	15
Deoxynivalenol in wheat	1000 to 4000	5
Ochratoxin A in foods	1 to 300	6
Patulin in apple juice	20 to 50	10
T-2 Toxin	100	2
Zearalenone	30 to 1000	4

Van Egmond, Current Situation on Regulations for Mycotoxins, Overview of Tolerances and Status of Standard Methods of Sampling and Analysis, *Food Additives and Contaminants*, Vol. 6, pp. 139–188. © 1989.

At present, the UK limits for foods include a guideline level of 50 μg kg^{-1} for patulin in apple juice and a statutory limit of 4 μg kg^{-1} for aflatoxin B_1 in nuts, dried figs, and their products used for direct consumption. The latter is relaxed to 10 μg kg^{-1} for these commodities intended for further processing on the understanding that such processing will reduce the level to 4 μg kg^{-1} (Statutory Instrument [1992] No. 3236). These figures will be reduced to 2 and 5 respectively from January 1999. There is also a statutory limit for aflatoxin in animal feeds that varies depending on the animals concerned but is now set at 5 μg kg^{-1} when the feed is to be used for young animals and dairy cattle (Statutory Instrument [1991] No. 177).

A recent MAFF Food Surveillance Paper[108] describes and tabulates results from surveillance carried out from 1986 to 1992. The report shows that it is possible to find some samples of foods containing levels of a number of mycotoxins in excess of the guideline or statutory concentrations, but the numbers are small. Such findings demonstrate the need for continuing vigilance and effective surveillance coupled with open discussion of the significance of any results and an open mind to the implications of setting maximum tolerated levels. A detailed assessment of the occurrence and significance of mycotoxins to humans in the countries of the European Community has been prepared by Smith et al.[170] This report is a valuable source of information on a wider range of mycotoxins than could be included in this chapter and is supported by an extensive bibliography.

53.8 CONCLUDING REMARKS

Mycotoxins produced as a result of the molding of inadequately stored postharvest food commodities

Table 53–13 Maximum Acceptable Levels for Aflatoxin for a Selection of Countries*

Country	*Limit (μg kg⁻¹)*	*Notes*
United Kingdom	4*	Nuts, dried figs, and their products
	10*	As above but intended for further processing
United States	20	Total aflatoxins in all foods
	0.5	Aflatoxin M_1 in whole milk, lowfat milk, and skim milk
Australia	5	All foods except peanut products
	15	Peanut products
India	30	All foods
Japan	10	All foods
China	50	Rice, peanuts, corn, sorghum, beans, wheat, barley, oats

* By the end of 1997, it is probable that the European Community proposals to reduce these maximum admissible levels for aflatoxin B_1 to 2 and 5 μg kg^{-1}, respectively, and to set a limit of 0.05 μg kg^{-1} for aflatoxin M_1 in milk, will come into force (DOC. VI/1669/97-rev. 4). These levels were agreed on in July 1998 and came into force in January 1999.

can reach concentrations that may have acute and chronic significance in the health of humans. This situation is most likely to occur in the tropical humid climates and will pose a problem for the poorer peoples of the world in developing countries. Mycotoxins also may be produced in the field before harvest at concentrations that may not be toxicologically significant; this phenomenon may be difficult to control. However, the ability to quantitatively detect very low levels, and concern over long-term effects such as carcinogenicity, genotoxicity, and immunosuppressive activity, have led to stringent advisory and legislative levels in a number of countries. These will have an effect on world trade and, although they may protect people in the wealthier parts of the world from exposure to mycotoxins, they may increase the problems for the developing countries, at least in the short term.

54.1 INTRODUCTION

Fish and shellfish poisoning are worldwide problems. Indeed, it appears that there is no part of the world ocean that does not experience periodic incursions of toxicity, which result in edible species of fish or, more commonly, shellfish becoming dangerous for consumption by humans and usually requiring government action to close, or greatly restrict, harvesting and distribution of affected shellfish or fish. Unfortunately, the incidence of toxic contamination seems to be on the rise because toxigenic microalgae, which are the primary source of the toxins, spread into previously unaffected areas.[36,115,128]

The foodborne illness discussed in this chapter is caused by consumption of fish or shellfish containing natural toxins derived from microorganisms and accumulated in the living animal, in most cases, through the food chain. The initiating factor usually is rapid multiplication of the toxigenic organisms, resulting in a bloom. The occurrence of the toxins is not consistent in any particular species of fish or shellfish but is a consequence of exposure of individual animals to toxin-producing microorganisms or toxin-carrying animals used as food. In general, the presence of toxin in fish or shellfish is not evidenced by any easily observed abnormalities in behavior or appearance of the living animal or of the separated tissues. Moreover, the raw or cooked flesh and other tissues appear normal and cannot be distinguished organoleptically from those of nontoxic animals. The toxins are relatively small organic molecules with a high potency for intoxication of humans but of little or no immunogenic capacity. There is no evidence of acquired immunity in any patient recovering from fish or shellfish poisoning and repeated episodes are common. The toxins typically are stable compounds unaffected by cooking or processing that pass easily into the internal tissues. Most are principally neurotoxins, but they often also give rise to gastrointestinal symptoms. Not infrequently, symptoms are due to mixtures of different toxic substances present in the animal tissues consumed by the patient. The toxins in such mixtures are usually chemically related substances but occasionally are quite different. This can give rise to variation in the reported frequency and types of symptoms.

Fish and shellfish poisonings are thus characterized by uncertainties and uncontrollable factors that are not encountered in most other microbiologically caused food poisonings. With one exception—scombroid poisoning—toxin accumulation occurs in the ocean and involves toxigenic microorganisms, usually microalgae, that are outside human control.

The principal intoxications resulting from seafoods having a microbiological origin include paralytic shellfish poisoning (PSP), diarrhetic shellfish poisoning (DSP), neurotoxic shellfish poisoning (NSP), amnesic shellfish poisoning (ASP) (also known as domoic acid poisoning), ciguatera, scombroid (histamine) fish poisoning, and puffer fish poisoning. PSP, DSP, and NSP are caused by toxins produced by dinoflagellates and ASP by a diatom toxin. These diseases typically result from consumption of bivalve mollusks that have been feeding on the toxigenic algae. Ciguatera is caused by eating fish from tropical waters that have accumulated toxins through a food chain. The toxin(s) causing ciguatera are derived from toxigenic microalgae growing in and around tropical coral reefs and are passed up the marine food chain through herbivorous reef fish to more far-ranging carnivorous species. Histamine or scombroid poisoning is caused by consumption of fish containing high levels of histamine (and other biogenic amines) resulting from histidine dehydrogenase activity of bacteria multiplying on the fish after death. Puffer fish (fugu) poisoning results from a toxin, tetrodotoxin, which is produced by bacteria probably growing in the intestine of the living fish.[113,127] A summary of the general characteristics of these poisonings is provided in Table 54–1.

54.2 SHELLFISH POISONING

The identification of microalgae capable of producing the various toxins and the toxins themselves implicated in human disease outbreaks from shellfish is a continuing process because the appearance or recognition of new toxic diseases and an increasing scientific investigation of both the microorganisms and the toxins is ongoing. There is some evidence that toxigenic microalgae are spreading into different coastal areas and the incidence of toxic blooms is increasing on a worldwide basis.[2] The causes of these phenomena may include the warming of waters in the Pacific because of the recurrent El Niño phenomenon and human effects such as translocation of species by ballast water and eutrophication from pollution.[2,4,37,109] The practical importance of all this for the working microbiologist is the necessity of keeping an open mind concerning the linkage of outbreaks to blooms of particular algae or other microorganisms in determining cause and in choosing a course of action.

Dinoflagellates are responsible for most shellfish poisoning. They are single-celled photosynthetic organisms that are approximately spherical, about 50 μm in diameter, and frequently are encased (armored) in a theca made up of connected plates. There are characteristically two grooves in the surface, one vertical and the other horizontal, around the middle of the plant, the girdle. The microorganisms are made motile by two flagella. There is a pore toward a pole of the cell, the apical pore. Dinoflagellates are designated as species largely on the morphological data of arrangement of thecal plates, groove shapes and alignment, and the appearance of the pore structure. Dinoflagellates are part of the phytoplankton that live and grow most commonly in the upper layer of the ocean, but some are benthic (bottom dwellers in shallow waters). They lie at the base of the food chain and are consumed by zooplankton such as copepods and by herbivorous fish, directly or indirectly. They are consumed by filter-feeding shellfish such as mussels, clams, oysters, and scallops near shore in shallow waters. Plankton-feeding fish may accumulate toxic dinoflagellates in the stomach and intestine during feeding.

54.2.1 Paralytic Shellfish Poisoning

Organisms and Their Toxins. PSP is not only the most widespread geographically of the marine toxications, but also is probably longest recognized and most widely studied. Cases due to consumption of mussels were reported in France as early as 1689 and later (1790–1903) in northwest America, the British Isles, Scandinavia, Japan, and South Africa.[39] However, the connection between the disease and toxigenic dinoflagellates was not recognized until the 1920s when the work of Meyer and Sommer[74,119] resulted in a specific test for the toxin and opened the field of research. Initially, it was thought that only dinoflagellates of the genus *Gonyaulax* were responsible for PSP;[102] however, *Prorocentrum micans* was implicated in a PSP outbreak in Portugal in the 1950s, and subsequently other genera and species of microalgae were shown to produce PSP toxins.[109]

The armored dinoflagellates *Gonyaulax* spp. (*Protogonyaulax*), now renamed *Alexandrium*, are probably the dominant cause of PSP outbreaks in temperate water regions. *Alexandrium catenella* (first identified as a PSP cause in 1937[119]) and *A. tamarense* remain the most frequently implicated species for PSP outbreaks in North America (Pacific and Atlantic coasts, respectively) and Japan and, to a lesser extent, Europe, South America, and elsewhere.[84,109] *A. minutum*, reported widespread distribution includes Egypt, North America, France, Spain and Portugal, Italy, Turkey, Ireland, the Netherlands, Australia and New Zealand, and the Baltic Sea.[16,27,38,109] Other *Alexandrium* species have been identified as toxigenic mostly in Europe but are less frequently encountered in PSP incidents involving human disease.

Gymnodinium catenatum is another PSP-causing dinoflagellate. First detected off Mexico in 1940, it was associated with repeated PSP outbreaks in Spain during the 1980s and subsequently with toxic outbreaks in Mexico, Japan, Portugal, and Tasmania.[3,35,38,73]

Pyrodinium bahamense v. *compressum* has been implicated in numerous PSP outbreaks, mainly from tropical areas. The organism originally was isolated in the Bahamas and was first identified as a cause of illness and deaths in outbreaks in Papua New Guinea.[67] Subsequently, it has been associated with recurrent outbreaks throughout the Indo-West Pacific region in the Philippines, Indonesia, Malaysia, Fiji, Guam, and other island communities in the area.[25,67] The outbreaks have been characterized by significant mortality and the unusual involvement of free-swimming fish as a source of the human intoxication. This is due to the regional practice of consuming pelagic, plankton-feeding fish whole with intestines included. There was a severe outbreak of PSP involving deaths in Guatemala in 1987.[100] This organism continues to present a problem in tropical areas among people who are greatly dependent on fish and shellfish for subsistence and as a livelihood.

Although not yet implicated in human PSP outbreaks, two fresh water cyanobacteria *Aphanizomenon flos-aquae* and *Anabaena circinalis* have been shown to produce saxitoxins.[6,44] *Anabaena circinalis*, when fed experimentally to an edible fresh water mussel, has been shown to cause accumulation of saxitoxins in the mussel tissues at levels toxic for humans and a similar accumulation was earlier demonstrated in *Mytilus edulis* fed *A. flos-aquae*.[83,105]

The possibility that bacteria may be involved in the production of PSP toxins has been raised repeatedly.[56] It has been reported that toxigenic algae in culture produce more toxin when bacteria are present than when grown axenically, and there have been claims that intracellular bacteria are instrumental in algal toxin production.[55,110] The evidence for this latter claim is weak, but bacteria isolated from unialgal cultures (sometimes supposed axenic) have been shown to produce PSP toxins. A strain identified as *Moraxella* sp. produced saxitoxin, which was detected by analysis of the growth medium by electrophoresis, thin-layer chromatography, high performance liquid chromatography (HPLC), and mouse bioassay.[55] Similarly, a *Bacillus* strain also produced PSP toxins in culture.[55,86] The evidence that *Alexandrium* spp. can produce toxin axenically seems well established, and at least one study refutes the claim that more toxin is produced when bacteria are present.[114] Moreover, recent genetic studies of toxin production support a hereditary basis for this in *Alexandrium*.[47] Nevertheless, the involvement of bacteria cannot be completely ruled out.[127]

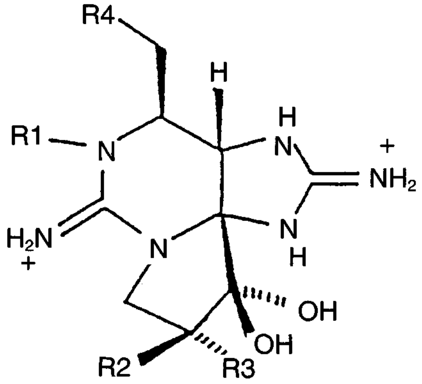
Saxitoxin, isolated from toxic Alaskan butter clams (*Saxidomus giganticus*), was long thought to be the major cause of PSP.[106] It is now known that the disease involves a family of toxins that may be considered derivatives of saxitoxin (Figure 54–1). There is an excellent discussion of the chemistry and pharmacology of this toxin group in the literature.[35,89] Toxigenic algae of the *Alexandrium* group show characteristic toxin profiles depending on the strain; this is probably genetically determined[14,15] and controlled by nuclear DNA.[47] The principal toxins found in algal strains implicated in human disease include saxitoxin, neosaxitoxin, and gonyautoxins 1 through 4, and these are most potent when tested by mouse bioassay. The B and C sulfocarbamoyl toxins are less toxic by an order of magnitude while the decarbomoyl derivatives are about half as toxic as the parent toxins.[11,115] This ranking is believed to correspond to the human response also.

All saxitoxins act by binding to the surface of voltage-activated sodium channels in nerve cells and thereby interrupt the flow of Na^+ ions, which stop signal transmission.[35,106] The details of attachment and the mechanism of blocking are still not fully understood. Attachment is apparently reversible since, except where death ensues, symptoms disappear within hours or days and no further toxic effect is observed.

The route of transmission of toxin to human consumers is quite direct.[35] The first event is the development of a toxic algae bloom resulting from rapid multiplication to populations of 10^3 or greater cells l^{-1} of seawater in response to suitable conditions. Unfortunately the nature of suitable conditions has not been determined except that in temperate regions' water temperatures above 14° C, and calm weather in spring, summer, and autumn usually are required. Blooms may be associated with discoloration of the water because of the large number of microrganisms formed. This often is referred to as red tide, but the color may range from red to brown or greenish shades. Red tides do not necessarily presage a toxic condition because a number of nontoxic microalgae and cyanobacteria can be involved, but they do indicate the occurrence of water conditions suitable for rapid microalgal growth. Most of the dinoflagellates causing PSP produce resting cyst

Table 54–1 Summary of Types of Fish and Shellfish Poisoning

Disease	*Food Vehicle*	*Agent Producing Toxin*	*Chemical Nature of Toxin*	*Symptoms*	*Occurrence*
Paralytic shellfish poisoning	Bivalve mollusks	Microalgae and bacteria in living shellfish	Saxitoxin, neosaxitin, gonyautoxins	Neurologic paresthesia, paralysis death by asphyxiation	Worldwide
Diarrhetic shellfish poisoning	Bivalve mollusks	Microalgae in living shellfish	Okadaic acid, dinophysis-toxin	Gastrointestinal diarrhea, nonlethal	Europe and Japan
Neurotoxic shellfish poisoning	Bivalve mollusks	Microalgae in living shellfish	Brevetoxins	Neurologic hot-cold reversal, paresthesia	US, New Zealand
Amnesic shellfish poisoning	Bivalve mollusks	Diatoms in living shellfish	Domoic acid, isodomoic acids	Neurological memory loss, gastroenteritis death by brain-stem damage	Canada, Western US, New Zealand
Ciguatera fish poisoning	Tropical reef fish and predators	Microalgae in reef vegetation	Ciguatoxins	Neurological hot-cold reversal, complex symptoms, not usually lethal	Tropical Pacific, Caribbean
Scombroid fish poisoning	Active (pelagic) free-swimming fish	Bacteria growing on fish after death	Histamine	Allergy like, and enteric symptoms, nonlethal	Worldwide
Puffer fish (Fugu) poisoning	Puffer fish	Bacteria associated with living fish	Tetrodotoxin	Neurological, anhydro-paralysis, paresthesia, death by asphyxiation	Japan, SE Asia, elsewhere



R1	R2	R3	Carbamate Toxins	N-Sulfocarbamoyl Toxins	Decarbamoyl Toxins

forms that persist in upper sediments or are suspended in water, creating seed beds that germinate to form active reproducing forms when conditions are appropriate. A phenomenon encountered increasingly in some temperate regions (particularly North America) is winter or cold-weather shellfish toxicity; this is believed to be due to mollusks feeding on cysts perhaps stirred from the sediment by storm surges. Cysts do contain toxin. In most cases molluskan shellfish ingest dinoflagellates or their spores from ambient water in their normal feeding mode, which is essentially passive, involving the filtering out of suitably sized particles. The ingested food passes more or less slowly through the alimentary and digestive system, and some toxin accumulates in the digestive glands or passes into internal tissues, though much passes directly out in feces. Most mollusks show a transient toxicity, which is lost within days, or at most weeks, after the bloom subsides. Some mollusks retain toxicity for longer periods; in particular, *Saxidomus* spp (eg, butter clams) store saxitoxin mostly in the siphon and may remain toxic for several months or, in extreme cases, for over a year.[12] Toxin passes to the human consumer directly from the ingested mollusk. Typically mollusks are consumed whole either raw or after cooking, which unfortunately does not affect the toxin. Illness ensues if enough toxin is ingested and the severity of the disease depends on the total consumed. Nevertheless, this is a very dangerous toxin and death in adult humans can follow ingestion of only 2 mg; individual shellfish have been reported to contain in excess of 10 mg.[84]

Characteristics of the Disease. This disease occurs most commonly in individuals who have eaten toxic mollusks, including mussels, clams, oysters, and scallops. In some cases in the Philippines and adjacent regions, the disease has resulted from consumption of whole plankton-feeding fish, including viscera. Since the PSP toxins are heat-resistant, both cooked and uncooked seafood can cause the disease. Symptoms appear between 5 and 30 minutes after ingestion of toxic mollusks (or fish), and their severity and prognosis depend on the amount of toxin consumed. Saxitoxins are among the most potent human poisons but it is difficult to determine doses necessary for symptoms to appear. Moreover, there is variability in the response of individuals, influenced by whether consumption was on an empty (more sensitive) or full stomach and whether oil (good) or alcohol were consumed. Another complicating factor is the variability in the actual mix of toxins in the consumed foodstuff. As has been noted earlier, there is strain specificity in the toxin profile of toxigenic dinoflagellates, and the pattern of toxin occurrence in different mollusk species feeding on the same dinoflagellate strain may also vary.[12,15,50,125] It appears from the literature that as little as 120 to 180 μg saxotoxin have caused moderate symptoms and 0.5–2 mg have caused death. Most regulatory authorities require that shellfish harvest cease when toxicity in mollusks rises to 80 μg STX 100 g^{-1} edible tissue.

In mild cases of PSP, patients experience a tingling or burning sensation of the lips, gums, and tongue that progresses to the neck, arms, fingertips, and toes and changes to numbness later. Occasionally, headache and dizziness are reported. In moderate cases, numbness extends to the arms and legs, making voluntary movements difficult; ataxia is accompanied by a peculiar feeling of lightness (floating on air). Aphasia, muscle pain, salivation, headache, thirst, nausea, and vomiting may occur. Severe poisoning causes progressive paralysis, ultimately leading to respiratory difficulty. Victims are conscious and aware throughout the illness. In untreated cases, paralysis may become progressively more severe, and death occurs due to respiratory paralysis, usually within 12 to 18 hours. If the patient survives beyond 12 hours, the prognosis is good and recovery generally is uneventful without sequelae.[39]

Treatment is mainly symptom directed and supportive. The stomach should be emptied by gastric lavage, and the patient placed in a respirator. Artificial respiration at the onset of symptoms is essential in severe cases and can prevent death even when very high doses have been ingested.[129] Toxin is apparently released from the site of attachment on Na+ channels and excreted without damage to nerves or tissues. Patients normally recover within hours or, at most, a few days. Nevertheless, it should be noted that saxitoxins are powerful and dangerous. Although death rates are low, perhaps less than 2%, in areas where shellfish regularly become toxic and the population is well aware of the risks and how to avoid them, rates as high as 23% have been reported in outbreaks occurring among uninformed populations. Statistics of global incidence of PSP are not readily available, but outbreaks are reported each year from different countries involving from a few to more than a hundred cases. The usual pattern is that an outbreak, often with deaths, alerts both local shellfish harvesters and regulatory authorities to the hazard and either warnings or an actual control system is put in place. Subsequently, there continue to be reports of toxic shellfish periodically in the region but disease incidence drops and deaths are rare. Where a mollusk culture industry is in place, control can be particularly effective because it is not in the best interest of growers that illness be associated with their products, and incidents of PSP poisoning almost exclusively involve recreational or subsistence gatherers.[84]

Food Vehicles and Transmission to the Consumer. The four shellfish poisonings—PSP, NSP, DSP, and ASP—share common features that determine the food vehicles and transmission routes to the consumer. Disease usually is due to the consumption of toxin-containing bivalve mollusks, such as mussels, clams, and oysters, all of which are sessile animals growing and feeding in fixed positions in or on the seafloor, on rocks, or attached to strings, rafts, or other containers in aquaculture operations. Some incidents have been due to slightly more mobile invertebrates such as scallops and snails; more rarely, crabs have also been implicated; however, these animals are quite limited in their feeding range. In many cases, the blooms of toxic algae are quite circumscribed, occurring in bays or other areas of confined waters where conditions are suitable for rapid and concentrated growth because of calm and undisturbed water. Outbreaks are thus often assignable to limited areas of origin where toxic mollusks are found. Moreover, in temperate regions, there is strong seasonality in the pattern of occurrence with most outbreaks occurring in summer and autumn when coastal water temperatures are elevated; this is true except in the case of ASP where the causal diatoms seem to bloom preferentially in colder waters. Microalgal blooms tend to be limited in duration corresponding to the persistence or otherwise of the water conditions supporting growth.

The risk to consumers of disease is thus confined, in the main, to shellfish eaters ingesting animals from toxic beds during periods of blooms. Once an area has been identified as toxic, the risk effectively disappears because harvest is then prohibited. Unfortunately, because of the stability of marine toxins, the risk from eating toxic mollusks cannot be reduced by cooking or otherwise processing the seafood. There is some reduction in risk by not consuming the viscera because a large proportion of toxin is usually in the stomach, intestine, and related internal organs, but this will not eliminate all danger because toxin may accumulate in clam siphons and other tissues. Mussels, clams, and oysters typically are eaten whole and are probably the most common vehicles of shellfish intoxications. In North America and, increasingly, elsewhere, only the adductor muscle of scallops are eaten and intoxications due to this mollusk are rare; however, in some countries the whole animal is eaten and the risk is correspondingly higher.

Saxitoxins have been identified in 110 species of sessile mollusks, ascidians, and barnacles; 27 species of decapods; 16 gastropods; 19 finfish; 1 cephalopod; and 1 starfish.[11] Fifty-four of these species have been involved in human disease; 34 in deaths. The frequency of involvement in human illness was calculated to be: clams, 35%; scallops, 24%; mussels, 21%; oysters, 12%; and cockles and others, <6%. The finfish species implicated in PSP all were involved in *Pyrodinium*-caused outbreaks in the Philippines, Indonesia, and Malaysia. PSP originally was known as mussel poisoning because these mollusks principally were involved in outbreaks recorded early in Europe and North America. They accumulate toxin more rapidly and to a higher level than other mollusks and they are tested as indicator animals for PSP in a number of countries. Indeed, mussel collection is prohibited during the summer months in California when the danger of toxic algal blooms is high.[84] Mussels also clear themselves of toxin rapidly when blooms subside, and toxicity in clams can persist longer, representing a potential danger if mussel results are relied on as a basis for closing and opening harvesting.

Detection and Control. The control of shellfish poisonings depends on surveillance of both waters and animals. This is possible because shellfish are localized along shorelines that are accessible to inspection and specimen gathering and because the presence of high numbers of causative, toxigenic microalgae becomes evident as a bloom in the inshore waters. Surveillance may involve collection of plankton samples, which are then examined for the presence of potentially toxic microalgae. If these are found, they are enumerated and, if sufficiently numerous, plankton samples may be tested directly for toxicity. Identification of toxic algae is mainly by direct microscopic examination of plankton samples and this requires expertise that may not be available in many small countries. Fortunately, the Intergovernmental Oceanographic Commission of UNESCO sponsors a number of training courses for field sampling and identification of harmful algae specifically for developing countries. Nevertheless, the identification of toxic microalgae can be difficult even for experts, and more objective methods that are less dependent on visual observation of whole cells are desirable. Methods based on isoenzyme electrophoretic patterns, toxin composition, and cell surface antigens all have been employed with variable effectiveness. Lectins have been applied effectively for typing bacteria and protists, and recently Costas and Rodas[19] have reported good results using fluorescent lectins for the identification of toxic dinoflagellates. Newer techniques for toxin analysis with very low detection limits facilitate the direct analysis of plankton samples.[9,92,117]

Shellfish may be sampled using a number of different protocols depending on the particular toxin(s) expected and such factors as season of the year, likely distribution of harvested shellfish, whether aquaculture or other commercial production is involved, and the extent of direct recreational or subsistence harvesting. Past experience of shellfishborne disease often will influence where and how frequently sampling and toxin testing are undertaken; however, recent experiences of sudden and unexpected incidence of novel toxicities in a number of countries in Europe and Australasia caused regulatory agencies to institute multiple toxin testing on a routine basis.[21,66] Toxin testing may be limited to so-called indicator species, most commonly mussels, which are generally the first to become toxic when a bloom occurs. Where commercial production of other species such as oysters is important, these species will normally be tested routinely (eg, the US). This is particularly important where cultured or commercially harvested shellfish are distributed to markets across state or international boundaries and cannot be recalled rapidly or embargoed if toxin is found. Where there is a high risk of toxicity, commercial producers may be required to submit samples for analysis before shipment. In some cases mussels are not suitable indicators (eg, for domoic acid in Washington state shellfish), and a broader range of shellfish should be tested. A determination that it is safe to resume harvest of shellfish for human consumption must depend on analysis of the actual species to be harvested.

The most widely used method of analysis is by animal testing, usually involving mice.[5] This has the advantage, from a public health standpoint, of measuring actual toxicity without regard to toxin composition, and, assuming that the effect on mice is equivalent to that on humans, it is the best test of risk. The symptoms shown by the mouse and the time to death can, when considered together with the source of the toxin, establish the toxin's identity. The results may be quantitated through dilution of toxin extracts and expressed as mouse units (MU) or as a chemical concentration when toxins have been purified. Extracts are prepared using appropriate methods for the expected toxins: aqueous for water soluble and organic solvents for others.

Methods for the extraction and testing of PSP toxins are well established and described in standard manuals such as the Association of Analytical Chemists (AOAC).[5] The extract is prepared by homogenizing shucked and washed shellfish meats in 0.1N HCl, boiling to precipitate proteins, diluting the cooled preparation, and centrifuging to clear precipitate. After appropriate dilutions calculated to achieve a death time of 5 to 7 minutes, 1 ml of the supernatant is injected intraperitoneally into the mice. Actual time of death is measured and converted into MU from a standard table. The assay requires a saxitoxin (STX) standard, which is available commercially. The MU for PSP is defined as the amount of toxin required to kill a 20 g mouse in 15 minutes. Mouse units may be converted to a quantitative measure defined as μg STX equivalent 100 g^{-1} tissue by multiplying by a correction factor, CF, which is 0.16 μg for the Webster strain of mice used in North America. Different values may be necessary for other strains (eg, 0.34 for the ddY strain used in Japan).[82] The method is wasteful of mice because of the need for testing multiple dilutions and there are other biological factors that contribute to the high average variability of ± 20%. Nevertheless this is still the officially accepted assay for determining mandatory closure of harvesting of edible shellfish in most countries, including the US.

Other animal assays for PSP toxins have been tested using house fly, cockroach, brine shrimp, finfish, and domestic chicken but none has proved sufficiently sensitive or practical for general use. Young chicks appear to have equal or greater sensitivity to PSP toxins as mice and have been used in emergency situations to test shellfish safety.[34] A number of assays that depend on measurement of the sodium channel-blocking effect of PSP toxins have been proposed, and most recently interest has focused on the method proposed by Kogure et al.[57] In this method, cultured mouse neuroblastoma cells are treated with the sodium channel activator veratridine in the presence of ouabain, an inhibitor of the Na^+/K^+ adenosine triphosphatase (ATPase). The effect is an elevation of intracellular sodium levels, causing swelling and eventual death of the cells. STX, by blocking Na^+ flow, protects against this effect in a dose-dependent manner, permitting quantitation. The original test required visual scoring of 200 or more cells per sample, which was quite tedious because of cell morphology variability. Two research groups independently developed colorimetric techniques to facilitate the use of dyes, crystal violet,[49] and neutral red[29] to stain the cells, permitting the use of microplates and automated reading of results. Most recently, a method making use of the reduction of a tetrazolium compound (3-[4,5-dimethylthiazol-2-y]-2,5-diphenyltetrazolium, Sigma) to a blue-colored formazan by actively metabolizing cells has been described and tested extensively.[69,70] This method also was reported independently by another research group.[138] The method is slower than the mouse bioassay requiring 24 to 48 hours but is animal-friendly, more sensitive, and convenient. This method also can be used for tetrodotoxin and Na^+ flow activators such as brevetoxins and ciguatoxins.

Perhaps the most widely used procedure for analysis of PSP toxins is HPLC. The method depends on a postcolumn derivatization of separated toxins to fluorescent compounds by oxidation under alkaline conditions. Current procedures are based on that described by Sullivan and coworkers;[124,126] the most recent method with widest recognition of STX and derivatives is that of Oshima.[89] The HPLC procedure provides for identification and quantitation of individual toxins and is particular useful for investigative and research purposes. Numerous immunoassay procedures for STX have been published, and commercial kits based on enzyme-linked immunosorbent assay (ELISA) methodologies are available in Europe and Canada; however, none has yet achieved general acceptance. This is due to difficulties in dealing with the various toxin mixtures produced by different strains of toxigenic algae and resulting from metabolically induced changes of toxins in shellfish tissues.[15,124]

54.2.2 Diarrhetic Shellfish Poisoning

Organisms and Their Toxins. DSP is perhaps the second most widely reported shellfish intoxication, but was only recognized in the 1970s from outbreaks in Japan and soon thereafter in Europe.[51,139] The disease is caused by ingestion of molluskan shellfish contaminated by toxins from the dinoflagellates *Dinophysis* spp. and *Prorocentrum lima*. Blooms occur in summer and autumn, and it has been reported that as few as 200 microalgae l^{-1} of sea water are sufficient to create toxic conditions in shellfish.[1] The duration of toxic blooms and persistence of toxins is longer than for most PSP incidents but the symptoms, which resemble those of gastroenteritis, are less severe.

The number of *Dinophysis* species implicated as sources of toxin has continued to increase as the DSP incidents have been reported in different parts of the world. *D. fortii* was the first implicated but *D. acuminata*, *D. acuta*, *D. mitra*, *D. norvegica*, *D. rotundata*, *D. sacculus*, and *D. tripos* all have been shown to be toxic.

Prorocentrum lima was associated early with incidents of DSP[81] and seems to be particularly prominent in mussel culture areas. It has a wide distribution being reported from Europe, North and South America, Japan, and New Zealand.[109]

The toxins causing the diarrhetic symptoms characteristic of DSP are polyethers, particularly okadaic acid, and dinophysistoxins shown in Figure 54–2. Other toxins have been identified in toxic *Dinophysis* spp. and in *P. lima*, including pectenotoxins and yessotoxins, all of which are also polyethers and are extracted by lipid solvents.[137] The chemistry and properties of the toxins are succinctly presented by Yasumoto et al.[138] Most commonly, okadaic acid (OA) has been reported as the primary cause of diarrhea in Europe and dinophysistoxin (usually I) in Japan, but both occur together. Pectenotoxins are reported to be hepatotoxic, and yessotoxins are highly toxic in mice, but neither group has been shown definitively to be active in human DSP.[137–139] The toxins show similarities to other polyether marine toxins specifically brevetoxins (NSP) and ciguatoxins (ciguatera). The profile of DSP toxins is somewhat variable among different strains, although OA seems to be present consistently. Quite low populations of dinoflagellates can cause shellfish to become toxic.

Characteristics of the Disease. This disease has been reported primarily from toxic mussels, but other bivalve mollusks including oysters and clams and scallops also have been implicated. The symptoms are similar to those due to gastroenteritis of bacterial origin, and this probably delayed identification of the syndrome until the 1970s. Patients have been reported to experience diarrhea (92%), nausea (80%), vomiting (79%), abdominal pain (53%), and chills (10%).[139] The symptoms appear 30 minutes to 12 hours after consumption of toxic shellfish, in most cases (70%) within 4 hours. Symptoms disappear within 3 days and there are no sequelae. This is thus a mild disease essentially without mortalities; however, because the two toxins principally involved—OA and dinophysistoxin 1—have been demonstrated to have potent tumor-promoting activity, there is concern that chronic exposure may induce tumor formation in the digestive system.[123] Pectenotoxins are highly hepatoxic and yessotoxin is highly toxic to mice, raising concerns about these DSP-associated substances although no human effects have been demonstrated.[138]

Toxigenic dinoflagellates producing DSP toxins are widespread through temperate waters of the world, but outbreaks of human disease due to DSP have been limited mainly to Japan and Europe. In Europe, DSP has been a particular problem for the mussel-growing industry in Spain and France. Several thousand cases occurred each year through the 1980s but the imposition of shellfish harvesting controls in the affected countries in recent years has greatly reduced incidence of DSP.[21,109]

Food Vehicles and Transmission to the Consumer. Diarrhetic toxins have been identified dominantly in mussels but also in oysters, scallops, and clams. Retention of toxins in mussels was reported to be very short—perhaps one week;[109] however, toxicity of mussels can persist possibly for a month or longer if sufficient populations of *Dinophysis*, which may be as few as 200 *Dinophysis* cells l^{-1}, are in the water.[1] Moreover depuration studies carried out in Italy indicated a requirement for >30 days in a pond system and >5 days when an ozonization technique was used to ensure elimination of the toxin.[20]

Detection and Control. In most countries where DSP has occurred, particularly in Europe (eg, France, Spain, Portugal, and the Scandinavian countries), surveillance by sampling coastal phytoplankton is maintained in areas of significant shellfish production.[21] Increasing numbers of toxigenic *Dinophysis* or *Prorocentrum* trigger increased testing of shellfish for DSP toxins and closure of shellfish harvest if toxin levels exceed action levels. ---

diarrheagenic toxins involved in DSP are OA and dinophysistoxins (DTX1-DTX3), but pectenotoxins and yessotoxin also may occur in toxic shellfish. A mouse bioassay for DSP based on the method originally described by Yasumoto[139] was used widely as the primary test for shellfish but was found to produce false-positive results due to contaminating fatty acids in shellfish digestive glands. A method that involves feeding tissue to white rats often is used.[51] A fluorometric HPLC method effectively identifies all of the toxins and their common derivatives when appropriate detection procedures are used.[7,60] In this procedure, digestive glands of shellfish are extracted with methanol, esterified to fluorescent esters with 9-anthryldiazomethane (ADAM), separated by HPLC, and monitored by fluorimetry. Toxin reference standards that are required for this method (OA, DTX1, DTX3) are now available commercially. Recently, useful modifications to improve sensitivity have been published.[95,138] The HPLC procedure easily detects concentrations below the legal limits used in Japan and Europe of 200 to 600 ng OA equivalent g^{-1} edible tissue.[95] A number of immunoassay procedures have been proposed and tested in recent years, and several test kits, primarily designed to identify OA, are available commercially in the US, Japan, and Canada.[92,138] New, improved procedures still appear in the literature.[20] There is disagreement concerning the usefulness of these and other proposed ELISA-type methods because of contrasting claims and experiences of too great a specificity on the one hand and insufficiently broad coverage on the other. A further complication is the occurrence of cross reactions between antisera for polyether toxins from different (defined) diseases (eg, ciguatoxins and okadaic acid), which is presented as an advantage or a disadvantage depending on the viewpoint of individual scientists.

54.2.3 Neurotoxic Shellfish Poisoning

Organisms and Their Toxins. NSP is caused by toxins produced by the unarmored dinoflagellates of the genus *Gymnodinium*. In the classical NSP outbreaks in the US, *G. breve* bloom in the Gulf of Mexico along the coast of Florida produced typical red tides and caused fish kills and toxic shellfish. Alternatively, the dinoflagellates may be entrained in the warm waters of the Gulf Stream and carried north off the US Atlantic coast. Blooms may be carried by eddies onto the Carolinas' beaches, producing red tides, fish kills, and toxic shellfish there.[132] Until recently, only one species, *G. breve*, was reportedly implicated, and outbreaks of NSP were confined to Florida and adjacent Atlantic states. However, in 1993, there was a large outbreak of shellfish poisoning in the North Island of New Zealand in which patients showed symptoms characteristic of NSP. The implicated dinoflagellate, though quite similar to G. *breve*, was determined to be a new species.[16,65] *Gymnodinium breve* produces a characteristic group of lipid-soluble polyether toxins, called brevetoxins, which act by opening Na+ ion channels, causing neurological symptoms. They are highly toxic to fish. The new species isolated from New Zealand waters produced closely related, but not identical, compounds. The unarmored *Gymnodinium* tend to be broken open by the pounding surf, which releases irritants that form an aerosol causing coughing and upper respiratory irritation in people on or near the beach.

The brevetoxins, shown in Figure 54–3, are methylated cyclic polyethers of two types, PbTx-1 type with a flexible backbone of 10 fused polyether rings and PbTx-2 type with a rigid ladder form of 11 rings.[94] They bind to a site in voltage-responsive sodium channels and essentially cause unintended firing of the neurons. Interestingly they seem to bind to the same sites as ciguatoxin.[8,94,120]

Characteristics of the Disease. The disease has been reported in individuals consuming oysters, clams, and other mollusks at the time of red tide occurrences in Florida and southern states along the US Atlantic coast.[8,132] In recent years, NSP has been reported in New Zealand.[65] Symptoms appear within minutes of consumption of toxic shellfish and generally subside within hours or, at most, a few days. Symptoms include tingling and numbness of the lips, tongue, throat, and perioral area; muscular aches and weakness; gastrointestinal upset; and dizziness. Some patients experience a reversal of hot and cold temperature sensation similar to that experienced in Ciguatera. This is not surprising since the brevetoxins responsible for NSP act by stimulating Na+ flow in voltage-gated sodium channels and attach to the same site as ciguatoxin. No fatalities and no sequelae have been reported. Concurrently with the shellfish-induced disease, there commonly are reports of upper respiratory irritation from individuals exposed to sea spray on or near beaches. This is a temporary and transient condition that does not involve the neurological symptoms of NSP.

Until 1993, outbreaks were only reported from the US, where they were sparse in recent years because of quick responses by regulatory agencies to fish kills related to red tides and closures of shellfish harvest. However, the outbreak in New Zealand involved an excess of 180 cases.[16] This illustrates the suddenness with which shellfish poisoning can occur and the sensitivity of unprepared populations.

Food Vehicles and Transmission to the Consumer. Brevetoxins are potent killers of fish; therefore, finfish are not involved in human NSP, which is invariably caused by consumption of shellfish. Clams, oysters, and bay scallops have been implicated.[109,132] *G. breve* toxins have been reported to persist for 2 to 6 weeks in the oyster, *Crassostrea virginica*.[77]

Detection and Control. Occurrence of this disease is controlled primarily by surveillance based initially on identification of characteristic red tides in Florida and the Gulf and South Atlantic states of the US. Plankton sampling and analysis is undertaken and when *G. breve* exceed 5,000 organisms l^{-1} of sea water, shellfish harvesting is closed. In the US, harvesting is reopened when no detectable toxin is measurable in shellfish tissues by mouse assay, but practically this may be interpreted as equivalent to <20 MU 100 g^{-1} of tissue.[132] In New Zealand, where NSP-like toxicities occurred in 1993, phytoplankton analyses are carried out on a regular basis as part of their toxin surveillance system and toxic *Gymnodinium* are one of the target groups. Molluskan shellfish are also tested for toxic-

ity.[16] If a toxic bloom is apparent, shellfish are tested immediately. The official test is by a mouse bioassay of methanol extracts of shellfish tissue. Time of death of the mice, together with characteristic symptoms, are used to determine toxin levels. State or national authorities normally close shellfish harvesting when toxin is found in shellfish; closure is maintained until no toxin is identified in repeated samplings. The isolation and identification of the brevetoxins in recent years[8] and their availability from commercial sources have stimulated research on chemical, immunological, and tissue culture assays for these substances. The mouse neuroblastoma cell culture technique using veratridine and ouabain described above for PSP toxin assay also has been proposed as a method for brevetoxins. Researchers have reported detection limits of 2 ng ml^{-1} in a 4 to 6 hour test, which is both more sensitive and faster than the mouse test.[70] Immunoassays are complicated by the fact that the toxins fall into two categories and include multiple epitopes so that it is necessary to use at least two specific antibody preparations for effective total assay.[9,24] An ELISA method that worked well for sea water and phytoplankton was described.[9] Complications arise because of the appearance of different brevetoxin derivatives and it has been suggested that further research is needed before any method can be adopted for general use.[138] The close chemical and pharmacological similarity between brevetoxins and ciguatoxins makes development of a common test seem both likely and useful.

54.2.4 Amnesic Shellfish Poisoning

Organisms and Their Toxins. ASP is the most recently recognized of the major shellfish intoxications, being first described in an outbreak in Canada in 1987.[133] The responsible microorganism is a pennate diatom belonging to the genus *Nitzschia* (now *Pseudonitzschia*), and the primary toxin is domoic acid. For this reason the disease often is called domoic acid poisoning. Outbreaks or toxic diatom occurrences subsequently have been reported from the Pacific coast of the US and from New Zealand and Europe.[22,64,65]

The *Nitzschia* group is a very large one, composed principally of nontoxin producers. Toxic species now have been assigned to the genus *Pseudonitzschia* originally named for *P. australis* isolated from Argentinian waters. There are now three well-recognized species: *P. pungens* (*F multiseries*) (from the original Canadian outbreak),[121] *P. australis* (shown to be the toxin source in the US Pacific states outbreaks),[13] and *P. pseudodelicatissima* (from Bay of Fundy, Canada).[71] Recently, toxigenic *N. seriata*, now named *P. seriata*,[64] was identified from Danish waters and it is probable that other species will be described. Toxic *P. australis* has been identified in New Zealand and is probably fairly widespread in colder southern hemisphere waters. *P. pseudodelicatissima* caused extensive blooms in Danish, Swedish, and Norwegian waters, causing toxicities in mussels. The organism also has caused blooms in the western Baltic. Unlike the dinoflagellates that flourish in warmer waters, *Pseudonitzschia* blooms occur at low water temperatures of 10° C or below; these blooms often reach much higher densities in excess of 1 million cells l^{-1}.

Domoic acid (Figure 54–4) originally was recognized as a toxic component of the red seaweed *Chondria armata* and has been used as a antihelminthic medicine in Japan. A series of isomers designated isodomoic acid A through F have been identified in plankton and of these D, E, and F are involved as minor constituents in ASP.[96] All are tricarboxylic amino acids and act as an analog of glutamic acid, a neurotransmitter in the brain.[133] At low-dose levels, the toxin induces mainly gastrointestinal symptoms such as vomiting, diarrhea, and abdominal cramps, but at higher doses causes neurological signs including confusion, memory loss, and other symptoms; hence the designation amnesic poisoning. Domoic acid binds to glutamate receptors causing increasing firing of neurones and eventually rupture of cells and can cause death, particularly in elderly patients.[133]

Characteristics of the Disease. Amnesic shellfish poisoning caused outbreaks of disease among consumers of mussels in eastern Canada in 1987 and of razor clams in Washington state in 1991. Over 250 reports of illness were documented in the Canadian outbreak, and 107 fitted the strict case definition.[133] Only 12 cases were reported in the Washington state outbreak. A presumptive outbreak has been reported involving only two people who had eaten canned smoked oysters in South Korea in 1992.[99] Initial symptoms typically include vomiting, diarrhea, and abdominal cramps and (often severe) headache. Neurological symptoms develop somewhat later in more severe cases and involve confusion, memory loss, disorientation, dizziness, and even seizures or coma. The reported frequency of common symptoms from the large Canadian outbreak was nausea (77%), vomiting (76%), abdominal cramps (51%), headache (43%), diarrhea (42%), and memory loss (25%). Severity of the symptoms seems to be correlated with age; older people are more susceptible to memory loss. Mild cases show only gastroenteritis or mild neurological effects and recovery is rapid and uneventful. Severe cases can show persistent neurological dysfunction for several months. In a few cases, mainly involving older people, damage appeared to be permanent.[133] Onset of ASP symptoms may be as soon as 15 minutes after consuming toxic shellfish or may be delayed as long as 38 hours. There were four deaths in the Canadian outbreak, but none in Washington[136] or Korea. Nineteen patients in the Canadian episode were hospitalized showing confusion, disorientation, and inability to remember the recent past. Twelve of the patients requiring intensive care exhibited neurological abnormalities including coma, mutism, seizures, chewing and grimacing, uncontrolled crying or aggressiveness, profuse respiratory excretion, and unstable blood pressure or cardiac arrhythmias.[93] Examination of the brains of patients who died after eating contaminated mussels revealed severe damage to the hippocampus and amygdaloid nucleus.[131] Domoic acid, the toxin causing ASP, is a structural analog to the excitatory amino acid neurotransmitter glutamate and binds very strongly to a glutamate receptor; this is thought to cause hyperexcitation, producing the initial neurological symptoms and leading to degeneration of the hippocampus and other related sensitive components of the spinal cord.

The onset and severity of ASP is obviously dose-related, and patients in the Canadian outbreak have been estimated to have ingested 60 to 295 mg domoic acid based on concentrations of 31 to 128 mg 100 g^{-1} in mussel tissue. No symptoms were reported by individuals consuming up to 20 mg domoic acid (0.3 mg kg^{-1} body weight). It has been calculated that patients with mild symptoms ingested 60 to 110 mg (0.9 to 2.0 mg kg^{-1} body weight) and those with severe symptoms consumed 135 to 295 mg (1.9 to 4.2 mg kg^{-1}).[133] This contrasts with the Washington state outbreak in which all cases exhib-

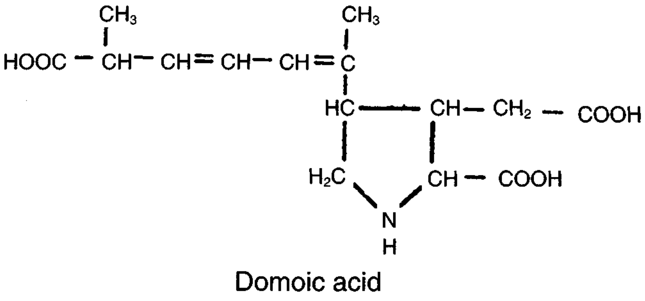

Figure 54–4 Amnesic Shellfish Poisoning Toxins. *Source:* Reprinted with permission from E.C.D. Todd, Domoic Acid and Amnesic Shellfish Poisoning—A Review, *Journal of Food Protection*, Vol. 56, pp. 69–83, © 1993, International Association of Milk, Food and Environmental Sanitarians, Inc. (IAMFES).

ited mild symptoms and ingested doses were only 0.05 to 0.39 mg kg^{-1} but unaffected persons ingested up to 0.28 mg kg^{-1}. No estimates were available for the Korean incidents.

Food Vehicles and Transmission to the Consumer. Domoic acid originally was associated with mussels in the Prince Edward Island ASP outbreak in 1987, but in subsequent years was recovered from the digestive glands of clams and scallops off Georges bank and the coast of Maine and from horse mussels and soft shell clams in Nova Scotia and New Brunswick.[133] In the US west coast incidents, domoic acid was identified in Californian anchovies (the source of illness and death of pelicans and cormorants) and later at low levels in mussels, and stone and rock crab viscera.[135,137] However, the toxin was detected at dangerous levels in razor clams in Washington state, causing several human ASP cases, and in Dungeness crab viscera.[22,44] Not surprisingly, the toxin later was reported from British Columbia, the Canadian province adjacent to Washington, from the same animals. Although the consequences of the sudden appearance of ASP in western North America were less severe in terms of human illness and death than the original Canadian episode, the occurrence deserves to be noted as a further warning of the risk presented by unexpected marine toxic incidents. The rapid and effective response by public health and other agencies in closing shellfish harvest and fish processing of anchovies was possible because of the existence of the PSP surveillance system in the affected states and provinces.[84] Domoic acid contamination of shellfish has been reported recently in New Zealand as a result of a routine screening program, with highest concentration and longest persistence in scallop viscera. *Pseudonitzschia australis* has been associated with the contamination, but a possibility that other benthic diatoms may be involved cannot be excluded.[66] This further emphasizes the need for alertness by regulatory and health authorities in coastal countries, particularly in northern and southern cold water regions, to the possibility of domoic acid contamination of shellfish. The foresight of authorities in New Zealand probably prevented human illness.

Detection and Control. Initially, ASP assays were conducted on mice using extracts prepared according to the PSP protocol. In positive cases, mice showed an involuntary scratching of both shoulders within 4 hours (typically 7 to 21 minutes) after IP injection, followed by increasingly uncoordinated movements and seizures. Death usually came within a few hours.[133] Unfortunately, mouse response was positive only for shellfish tissue levels of >40 µg domoic acid g^{-1} wet weight, well above the regulatory level of 20 µg g^{-1}. Consequently, an HPLC method has been adopted as the method of choice for analyzing shellfish samples for domoic acid.[59,133] This has an effective limit of 1 µg g^{-1} of tissue but lower levels are obtainable by modifying extraction methods.[95] Analytical methods used in different countries are detailed in a recent publication of IOC.[96] Recently, an ELISA type immunoassay has been described using standard PSP type extracts with lower limit of detection below 0.5 µg g^{-1}.[114] The authors indicate that the test would be suitable for field testing.

54.3 FISH POISONING

Human poisonings from toxic fish differ from shellfish poisoning in a number of ways. They generally are caused by consumption of flesh from a single animal, so outbreaks involve a limited number of people, while shellfish incidents usually involve consumption of several toxic animals and outbreaks may be large. The mobility of fish makes identification of toxic focii difficult except in the case of scombroid poisoning, which develops in dead animals after capture, while beds of toxic shellfish are readily located. The origin of fish toxins also is more varied than shellfish toxins involving bacteria as well as dinoflagellates. It is noteworthy that human poisoning has occurred as a result of eating fish contaminated with PSP toxins,[67] and marine bird and mammal intoxications have been associated with

Next Page

consumption of fish that have fed on toxic (PSP and ASP) phytoplankton.[133] There is good reason to believe that in these cases toxin was derived from toxic plankton residues in the fish intestine rather than the muscle tissues normally eaten by human consumers. The fish poisonings discussed in this section are caused by eating toxic muscle tissue, though in fish causing ciguatera and puffer fish poisoning, viscera can be a potent source of toxin and may physically contaminate edible flesh.

Because of the dispersed distribution of toxic fish in the environment, there is very limited regulation of harvest, and human protection depends mainly on general warnings issued periodically to the industry and consumers. However, landing, sale, and distribution of particularly dangerous species may be prohibited in particular countries or regions either seasonally or on a permanent basis and there are special regulations regarding puffer fish in Japan.

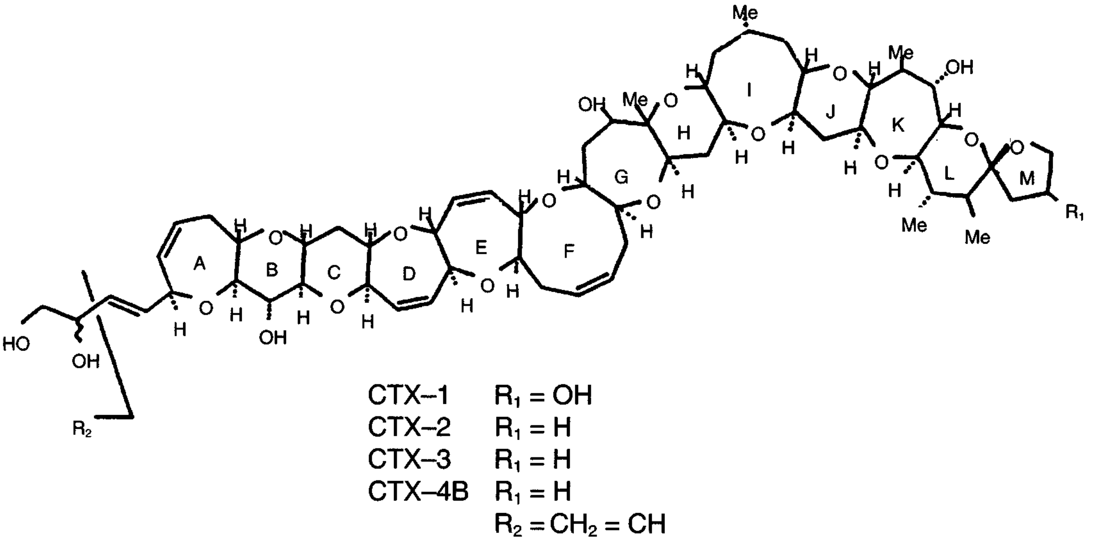
54.3.1 Ciguatera

Organisms and Their Toxins. Ciguatera is caused by ingestion of tropical or subtropical fish species that contain ciguatoxin and related toxins originating from the dinoflagellate *Gambierdiscus toxicus.* This toxigenic microalga is benthic and commonly is isolated from macroalgae growing on or near coral reefs. Recently, the organism has been isolated from seaweed growing on a sandy bottom in tropical Australian waters.[62] Herbivorous fish and invertebrates grazing on the reef vegetation or on benthic macroalgae ingest *G. toxicus* when present and accumulate toxin in the alimentary canal and in the tissues. The herbivores frequently are prey of carnivorous species, which may then become toxic by toxin transfer. Secondary carnivore-carnivore predation leads to progressive accumulation of toxin continuing through the life cycle so that large fish are typically more poisonous than smaller fish of the same species.[33]

Gambierdiscus toxicus is a slow-growing dinoflagellate that is an epiphyte of other macroalgae, does not produce cysts, and has been reported to be capable of growth at water temperatures of 20° C to 34° C, in salinities from 2.5% to 4%, and at depths from 0.1 m to 30 m.[62] It is a characteristic of ciguatera that the occurrence of toxic fish on reefs is variable. Some reef areas tend to be more frequently implicated than others as toxin sources, but there is a degree of unpredictability concerning toxic sites that suggests the growth of *Gambierdiscus* is influenced by changing environmental conditions.[62] It has been reported that population density of *G. toxicus* in nature increases and decreases rapidly without regard to seasonal changes. There are indications that degradation of reef integrity, sometimes due to human activity, results in upsurges in ciguatera but the mechanism of these effects is not understood.[101]

The major toxins in Pacific fish causing ciguatera appear to be ciguatoxins, but other toxins may be concurrently present including scaritoxin and maitotoxin. Yasumoto et al. provide a useful overview of these toxins;[138] their structures are shown in Figure 54–5. The ciguatoxins are lipid-soluble polyethers believed to derive from toxins (sometimes called gambiertoxins) that are produced by *G. toxicus* as a result of biotransformation occurring during transfer to fish or within fish tissues.[62] At least six congeners labeled CTX 1-4, 4A, and 4B have been identified; CTX1, or simply CTX, the ciguatoxin originally identified by Schauer's group,[107] is the principal toxin encountered in cases of ciguatera. These toxins are potent activators of voltage-dependent sodium channels in nerve cells and produce essentially neurological symptoms in humans. Scaritoxin is as yet uncharacterized but could be a gambiertoxin derivative. Maitotoxin, produced in large quantities by *G. toxicus*, is a polyether toxin that activates Ca^{2+} release influencing muscle contraction. It is found particularly in small herbivorous fish.[138] This toxin has powerful effects on mice (LD_{50} for mice by IP, 50 ng kg^{-1}), but its toxicity for humans has been questioned. Other toxins identified in ciguateric fish include OA and palyotoxin; these are obviously derived from sources other than *G. toxicus* and it is unclear whether they participate in the ciguatera syndrome.[53,54] A further complication in toxin identity and function arises from the fact that Caribbean outbreaks of ciguatera show a different balance of symptoms than Pacific cases, suggesting that different toxins may be involved. This is supported by the poor success of an immunochemical test that worked well for ciguatera toxins of Pacific fish in identifying toxic Caribbean fish;[91] nevertheless, polyether type toxins are indicated in all cases.[62]

Characteristics of the Disease. This disease is a clinical syndrome consisting of gastrointestinal and neurological symptoms occurring after consumption of ciguatoxic fish. The gastrointestinal symptoms appear 3 to 5 hours after ingestion of ciguatoxic fish and are soon resolved, while neurological symptoms that begin 12 to 18 hours after consumption may be



CTX–1 $R_1 = OH$
CTX–2 $R_1 = H$
CTX–3 $R_1 = H$
CTX–4B $R_1 = H$
$R_2 = CH_2 = CH$

Figure 54–5 Ciguatera Toxins. *Source:* Reprinted with permission from R.J. Lewis and M.J. Holmes, Mini Review, Origin and Transfer of Toxins Involved in Ciguatera, *Comparative Biochemistry & Physiology,* Vol. 106 C, pp. 615–628, © 1993, Elsevier Applied Science.

moderate to severe and normally last for 1 to 82 days. A wide range of symptoms has been reported, including nausea; vomiting; diarrhea; prickling of the lips, tongue, and throat; numbness; headache; arthralgia; erythism; dizziness; cyanosis; insomnia; prostration; ataxia; and myalgia. There is severe pain, particularly in the arms, legs, and eyes, vision disturbances, and teeth feel loose. Skin disorders appear, including erythema, maculopapular eruption, blisters, stinging sensation, and loss of hair and nails. The neurotoxic symptoms are most pronounced in severe cases and often include the characteristic reversal of temperature perception where cold is perceived as hot ("dry ice" or "electric shock" sensation) and hot objects are perceived as cold. General motor incoordination, paralysis, and convulsion progressively become worse, sometimes progressing to coma and death. The fatality rate is, however, low and the majority of cases are mild and resolve within a few days or weeks; in more severe cases, recovery can be slow, extending over months or years.[58,75,134] Recurrence of some symptoms is not uncommon, stimulated by alcohol consumption or sometimes by eating fish. The variety of symptoms reported suggests that more than one toxin is involved.[53] Treatment of ciguatera is designed to relieve the more severe symptoms; intravenous mannitol infusion recently has become the treatment of choice in acute cases; atropine may be used for symptomatic bradyarrhythmias. A variety of drugs has been tried for management of chronic symptoms including amytriptyline and tocainide, with variable success in individual patients.[58,90,134]

Ciguatera is reported principally from tropical regions, particularly island communities of the tropical Pacific and Caribbean oceans, but also from Australia, India, and other countries with warm-water coastlines. Incidence of cases in the island communities in which fish is an important component of the diet is high with estimates of several events in the lifetime of residents. Actual incidence was calculated to be 730/100,000 population per year (1970s) in the Virgin Islands,[75] 234.9/100,000 population in the Marshall Islands (1980s),[101] and 50 to 500/100,000 in Miami. Regalis, in 1984,[97] reported an estimate of 50,000 cases/year globally while a more recent estimate (1993) suggests in excess of 25,000 cases/year.[62] Obviously the true incidence of ciguatera is very difficult to determine because of the wide distribution of cases and the absence of good reporting systems or records in many locales. There has been a surge in interest in the disease because of numerous incidents involving tourists in island resorts and because of an increase in reports of ciguatera in nontropical countries, caused by imported fish caught in areas of ciguatera incidence.[46]

There is still some uncertainty concerning the diagnosis of ciguatera and the role of various toxins in its pathology. The principal toxins identified in ciguatoxic fish include ciguatoxins 1, 2, and 3, scaritoxin, and maitotoxin, but okadaic acid and even palytoxin as well as other water-soluble toxins have been reported in some cases.[23,24,48] Ciguatoxins are dominant in ciguateric fish from the Pacific regions[62] and probably also Caribbean species, and their known ability to bind to sodium channels and promote activation can account for much of the neurological effects observed in patients. It has been proposed that ciguatoxin causes a nerve conduction block after the initial neural stimulation.[32] Scaritoxin is another lipid-soluble toxin that has a depolarizing action on excitable membranes and also depresses oxidative processes in rat brain.[61] This toxin was identified as the cause of delayed ataxia in a case involving ciguateric parrotfish.[17] OA has been suggested as a factor accounting for the increased incidence of gastrointestinal signs in ciguatera caused by Caribbean fish as compared with Pacific species.[31] Palyotoxin is a polyether toxin and causes clinically distinguishable symptoms from ciguatera, but a mild palyotoxin episode might simulate ciguatera.[54,62] Recent studies of the application of a new commercially available immune bead test for ciguatera that appears to pick up a variety of polyether toxins has pointed toward a rather general incidence of polyethers, including brevetoxins in fish from ciguateric areas, but dominantly OA. This brings into question the specificity of ciguatera as a single definable disease or its existence as a useful description of a somewhat variable syndrome.[91,92] It also is possible that the identification of *G. toxicus* as the sole origin of ciguatera toxins is not correct; other dinoflagellates have been implicated in the past,[62] and recently the cyanobacterium *Trichodesmium erythraeum* has been shown to produce ciguatera toxins.[24] Whether a single origin or not, the condition is of widespread occurrence in the tropics and has both important human and economic consequences for individuals and society.

Food Vehicles and Transmission to the Consumer. More than 400 species of fish have been listed as potentially ciguateric.[33,39] The fish most commonly implicated in outbreaks reported to the U.S. Centers for Disease Control and Prevention (CDC) 1978 to 1987 were amberjack (*Seriola*), snapper (*Lutjanidae*), grouper (*Serranidae*), goatfish (*Mullidae*), Jacks (*Carangidae*), and barracuda (*Sphyrenidae*).[46] Most frequently involved elsewhere were *Scombroididae* in Australia, *Sphyrenidae* in Fiji, and *Acanthuridae* and *Serranidae* in French Polynesia.[33,58,134] The possibility of ingesting a ciguateric fish is quite high for fish eaters in certain areas of the world, specifically the islands of the tropical Pacific, the Caribbean and adjacent countries, coastal India and Asia, Australia, and anywhere adjacent to tropical reefs. Indeed, the ubiquity of toxic fish in particular locations, and the necessity of fish as an accessible and affordable source of animal protein for local inhabitants, make repeated experiences of ciguatera almost inevitable. Because the disease rarely is fatal and ultimately is self-resolving in most cases, there is a low level of attention by local regulatory authorities, although sale of known dangerous species is banned in some cases (eg, groupers, snapper, barracuda, and surgeonfish in French Polynesia[33] and barracuda in Florida). The risk for the traveler or tourist can be equally high, and government agencies in favorite tourist locations (eg, Caribbean Islands) as well as some international organizations and the tourist industry attempt to provide information and warnings to incoming visitors.

Detection and Control. Fish poisoning due to ciguatera toxins obviously cannot be dealt with like shellfish intoxications. Toxin accumulation occurs through a food web of wide distribution and involving mobile components. Although it is possible in isolated island groups in the south Pacific to track toxin sources to a particular reef or even parts of a reef, the task becomes more difficult when the number of adjacent islands is large or the fishing area is extensive. Tracking large, mobile, predatory fish to a toxin source is even more improbable and not particularly useful for any practicable control. Unfortunately, at the present time, toxic fish usually are identified when they cause human illness. Some control is achieved by banning the landing or presentation for sale of certain high-risk species in regions where ciguatera occurs (eg, barracuda in Florida; groupers, barracuda, snappers, and surgeonfish in French Polynesia; amberjack in Hawaii),[33] but the free movement of most species in international commerce makes the deliberate or accidental circumvention of such rules almost inevitable, and so cases of ciguatera continue to occur in tropical island communities and widely among importing countries. Truly effective control requires that toxic fish be recognized and intercepted at some point between capture and the consumer's plate. This requires an effective and preferably simple, inexpensive, and a nondestructive test for toxicity that can be performed at point of capture, landing, or sale.[46] Such a test could be applied individually to each of the larger fish of likely ciguateric species that usually constitute the major problem and normally are caught by hook and line.

A variety of animals were used to test for ciguatoxic fish prior to the isolation and chemical identification of CTX by Scheuer and his group in 1967.[107] Thereafter, a more definitive mouse assay was used for this toxin and its analogs. Toxins are extracted from fish tissues using lipid solvents, such as methanol, diluted, and injected IP into mice. Typical symptoms develop, and death occurs over a 24 to 48 hour period. Symptoms include diarrhea within 15 minutes, dyspnea and cyanosis later, penis erection, and dyspnea-derived convulsion before death.[130] Body temperature also may be depressed. Quantitative assay may be obtained by using dose survival time data for pure toxin. One MU is equivalent to 7 ng CTX, and as little as 10 MU have been reported to cause poisoning.

Fluorescent esters may be made of CTX, and this has formed the basis of a liquid chromatographic method for estimating some, but not all, of the CTX toxin group.[138] The method worked well with carnivorous fish; however, there is a problem in detecting low toxin levels that can cause ciguatera (eg, 35 ng 100 g^{-1}), especially in herbivores in which toxins lacking the reactive group to produce fluorescent esters are more abundant.

The cell assay system using mouse neuroblastoma cells described earlier for analysis of saxitoxins and brevetoxins can be used for ciguatoxins. Two groups of scientists have shown this method to be highly sensitive for CTX toxins, detecting from 0.1 to 5 nmole CTX kg^{-1} in toxic flesh fish.[70,138] The method was reported to correspond well with mouse bioassay (though much more sensitive) and to be indifferent to the regional source of the ciguateric fish, whether Pacific or Caribbean.

A number of immunoassay procedures for ciguatera have been described in the scientific literature,[91] and some are under collaborative study. Perhaps the longest series of studies are those of Hokama and his colleagues culminating most recently in the commercially available Ciguakit based on a monoclonal antibody specific to ciguatoxin, OA, and a fragment of OA.[40–42] This system thus can be used to detect toxins of ciguatera and DSP. The method has reportedly worked well for ciguateric Pacific fish and DSP shellfish in Europe,[92] but has been less successful with ciguateric fish from the Caribbean. Another series of studies of immunoassay procedures by a group at the University of Miami has culminated in an ELISA system based on two antibodies that are targeted at brevetoxins and ciguatoxins but do not cross react with other polyether toxins such as OA and dinophysistotoxins.[9] The system has been shown to work well for dinoflagellates and isolated toxins but not for fish or shellfish.

54.3.2 Scombroid Fish Poisoning

Organisms and Their Toxins. This disease differs from all other natural fish poisonings because the toxin is produced in the fish post mortem and thus is potentially controllable. Moreover, bacteria, probably of human origin because they are not natural inhabitants of the oceans, are the most probable cause of the toxicity, which appears to be histamine poisoning though other amines may be involved.[52] Originally, it was thought that the problem only occurred in fish of the *Scombridae* (mainly tunas and mackerels)—hence the disease name—but subsequently, it became clear that a much wider range of fish is involved, including many pelagic, rapid-swimming species with relatively high natural tissue levels of free (unbound) histidine; a common and nutritionally desirable amino acid. Histamine is produced in such fish post mortem as a result of growth of bacteria that produce histidine decarboxylase. When fish are held at cool temperatures (<10° C), the rate of production of histamine is slow and the concentration at the point of rejection for spoilage is normally below the danger level of 50 mg histidine 100 g^{-1} fish tissue.[28,87] This corresponds to growth of psychrotrophic spoilage bacteria that are slow histamine producers. Storage of fish at higher temperatures (>15° C) results in more rapid production of histamine with levels of >100mg 100g^{-1} reached before spoilage rejection.[10] In this case, the bacteria dominating the fish microflora are mesophilic and include strong histamine producers.[10,87] Arrhenius plots of histamine formation and—separately—of organoleptic spoilage in stored scombrotoxic fish show deviation from linearity between 5° C and 10° C, confirming involvement of distinct psychrophilic and mesophilic bacteria below and above this temperature range.[10,63] The bacteria most commonly implicated in scombroid poisoning are members of the Enterobacteriaceae; specifically, *Morganella morganii*, *Klebsiella pneumoniae*, and *Hafnia alvei*, but *Clostridium perfringens* also may be involved in some cases.[130] These bacteria grow rapidly at temperatures above 20° C and characteristically produce active histidine decarboxylase resulting in accumulation of significant levels of histamine in the tissues of dark fleshed fish. They are not normally part of the microflora of living fish, except for *C. perfringens*, which is found in the intestine of fish caught in inshore waters. Thus, it is probable that these bacteria are contaminants from handling the fish after its capture. Clearly, the fish must be exposed to warm temperatures after contamination for the few hours necessary for histamine to be produced and accumulate to a toxic level if scombroid poisoning is to occur in individuals eating the fish. In most cases, fish involved in such poisonings have been found to have levels of histamine >100 mg 100 g^{-1} of muscle tissue; however, there have been reports of fish with much lower histamine levels causing poisoning. It should be noted that the normal course of spoilage in pelagic dark-fleshed fish held under refrigeration temperatures (<5° C) usually results in the production of histamine, but at levels below those causing illness (eg, <20mg 100 g^{-1} of fish tissue).

The substance primarily implicated in scombroid poisoning is histamine, and the initial symptoms, which to some extent mimic an allergic response, support this conclusion.[102] The amount of histamine apparently ingested by patients showing the symptoms sometimes is less than the amount shown to be necessary by experimental administration of histamine to volunteers. Japanese scientists initially identified saurine, a substance with histamine-like properties, as the cause of the disease, but this was shown to be an artifact of the separation technique.[26,52,111] The decarboxylase activity of bacteria growing on the fish post mortem results in accumulation of other amines, including cadaverine and putrescene, which have been shown experimentally to enhance the toxic effect of histamine. Specifically, it has been proposed that there is partial inhibition of the natural histaminase activity in the alimentary canal or interference in its function. An alternative proposal by one group of researchers, based in part on human volunteer studies, is that some component in scombrotoxic fish, perhaps an algal toxin, causes human mast cells in situ to produce histamine, thus giving rise to the characteristic symptoms.[18,45] These findings have been contradicted by other observations that indicate histamine is not produced endogenously by this mechanism in patients,[76] and the view that currently prevails is that scombroid poisoning is a result of histamine accumulated in fish as a consequence of temperature control failure at some point between capture and consumption.

Characteristics of the Disease. This is a disease of truly worldwide incidence, although it is more frequently associated with fish from warm-water regions than temperate species. As noted earlier, it differs from the other seafood intoxications in being caused by the activity of bacteria accumulating toxic histamine (and perhaps other active substances) as a consequence of metabolic activity in or on dead fish after capture. Symptoms appear a few minutes to an hour after consuming the toxic fish and initially resemble anaphylaxis. They include a metallic, sharp, or peppery taste; intense headache; dizziness; nausea; vomiting; facial swelling and flushing; epigastric pain; throbbing of carotid and temporal vessels; rapid and weak pulse; burning throat; thirst; difficulty swallowing; edema; itchy skin; audible wheezing; and diarrhea.[102] In most cases, the symptoms disappear quickly, with complete recovery in 10 to 12 hours. Specific treatment usually is unnecessary but oral antihistamines may be beneficial in severe cases.[102] Fatalities are unusual and usually due to other, unrelated contributing causes.[130]

Scombroid fish poisoning is the principal cause of fish poisoning in the US and is commonly reported from many other countries. Because the symptoms are so transient and, in most cases, so mild, this poisoning frequently is not reported to public health authorities, making it difficult to obtain realistic estimates of the true incidence. Improvements in handling of tuna destined for canning and screening of raw fish for histamine content by commercial canners virtually have eliminated scombroid poisoning due to canned tuna, but fresh and frozen tuna still cause poisoning incidents. The incidence of reported cases of scombroid poisoning in various countries until 1982 is listed in Taylor.[130] He notes that statistics are fragmentary for most countries but gives numbers for Japan, the UK, and the US. Early Japanese outbreaks were characterized by high case numbers; during 1951–1954, there were 14 outbreaks with 1,215 cases (including 1 outbreak with 700 cases), while during 1970–1980, there were 42 outbreaks involving 4,122 cases (with 1 outbreak of 2,656 cases). Taylor reports 136 outbreaks in the UK for 1976–1982, with a total of 439 cases indicating much smaller sized outbreaks. Small outbreaks were also reported in the US, where between 1968 and 1977, 55 reported outbreaks involved 516 cases. A later report for the US[46] indicated 157 cases with 757 cases in the period 1978–1980, confirming a continuing trend for small-sized outbreaks. Scombroid poisoning has now been reported from virtually every country in the world and, though reliable estimates of total world incidence are not available, cases annually must total in the thousands.

Food Vehicles and Transmission to the Consumer. The number of fish species reportedly involved in scombroid fish poisoning continues to increase as reports appear from different countries around the world. The majority of incidents involve scombroid fish, particularly mackerels and tunas (including bonito) and nonscombroids such as dolphinfish or mahi mahi (*Coryphaena hippuris*), sardines, anchovies, pilchard, herrings, Atlantic bluefish (*Pomatomas saltatrix*), marlins, and yellowtail (*Carangidae*).[80,132,134] More generally, marine pelagic fish with characteristically dark meat are likely to be involved. This is truly a disease of worldwide incidence, but the risk may be highest for fish caught in warm waters and exposed to high ambient temperatures after capture. Processes that involve heating the fish to temperatures that promote the growth of mesophilic bacteria such as smoking or sun drying can cause accumulation of histamine to dangerous levels if proper controls are lacking. Moreover, since histamine is not destroyed by heat processes used in canning, canned fish can be a vehicle for scombroid poisoning. Thus the risk to consumers depends on both the species of fish and the quality of handling and processing. Risk could in theory be eliminated by testing all fish of incriminated species for histamine since several analytical procedures are available for this substance. Obviously, this is impractical and usually only fish in batch-type operations such as tuna for canning or species likely or known to have been mishandled are tested.

Detection and Control. The analytical procedures for scombroid fish poisoning are limited to methods for histamine because no other compound has been demonstrated to indicate toxicity convincingly. There are a number of reliable analytical methods for histamine but the most widely used is the fluorometric procedure described in AOAC.[6]

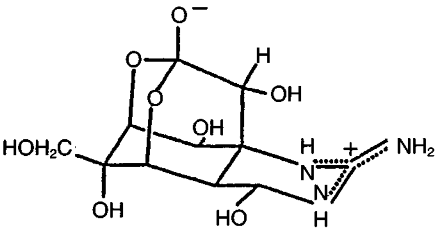
Control of scombroid poisoning is dependent on proper handling of fish after capture and during storage, processing and transportation, and the interception and removal from the food supply of fish with high histamine content (>5 mg 100 g^{-1} fish) before it reaches the consumer. The usually mild and self-resolving nature of scombroid poisoning precludes large investment in routine analysis of potentially toxic fish. It is, therefore, likely to be much more productive to emphasize the importance of rapid chilling of fish after death, maintenance of low temperatures during storage and, where possible, during processing. All fish should be held as close to 0° C as possible to limit the rate of spoilage as a matter of good commercial practice. Histamine development to levels causing symptoms is due to the growth of mesophilic bacteria producing copious amounts of amino acid decarboxylases in or on fish, which have high levels of free histidine. This clearly indicates that the flesh temperature of the fish has exceeded 15° C over a period of at least 12 hours. For large fish, such as tuna, caught in warm surface waters and with a body temperature often exceeding 25° C, this would not be an unusual situation unless specific measures are taken immediately after capture to cool the fish quickly. The time necessary to cool single large fish or bulked smaller species with inadequate chilling procedures (eg, top icing) is frequently underestimated. Moreover, intermittent inadvertent reheating of fish during transport or processing (eg, smoking) can create conditions for bacteria and amino acid decarboxylases to accumulate or become active. Some enzyme activity has been shown to continue during cool storage and may be sufficient to increase histamine above toxic levels.[63]

54.3.3 Puffer Fish (Fugu) Poisoning

Organisms and Their Toxins. Puffer fish poisoning results from the presence of tetrodotoxin in the tissues of puffer fish.[78] The name puffer fish was given because these fish characteristically swallow air or water to inflate their spiny bodies when threatened, probably as a disincentive to predators. Certain species are considered a delicacy in Japan and other Asian countries. The toxin is not consistently present in fish, but is most concentrated in the liver and other internal organs and unevenly present, in lesser amounts, in the muscle. Tetrodotoxin (TTX) is most prevalent in and near the gonads, particularly during the spawning season.[134] TTX also has been isolated from a number of other animals including goby fish, newts, frogs, octopus, ivory shell, trumpet shell, starfish, flatworms, various crabs, and gastropods, some of which have been involved in human poisonings.[78,134,141] Puffer fish cultured under controlled conditions are nontoxic but can be made toxic by feeding them liver from toxic fish, suggesting a food chain origin for the toxin;[103] however, bacteria that produce TTX and dehydrotetrodotoxin have been isolated from the skin and intestine of puffer fish and other sources.[85,122,140,142] The toxigenic bacteria originally were identified as *Pseudomonas* and *Vibrio* spp., particularly *V. alginolyticus*, a common bacterium on fish and shellfish.[113] Tamplin[127] lists 21 bacterial species reported to produce tetrodotoxins, including *Vibrios* (9), *Alteromonas* (5), *Aeromonas* (2), *Plesiomonas* (1), *Pseudomonas* (1), and *Escherichia coli* (1).[127] More recently, three of the toxigenic strains isolated from red algae and puffer fish were identified definitively as *Listonella pelagia* (*V. pelagius*), *Alteromonas tetraodonis*, and *Shewanella alga.*[112] *Vibrio* spp. typically occur in the intestine of marine fish, and it has been shown to dominate the microflora of puffer fish (*Fugu niphobles*) when the fish were reared in water at 29° C. It has been proposed, therefore, that TTX-producing bacteria growing in the intestine of puffer fish are the source of the toxin in these fish and more generally of toxin in the other TTX-containing animals.[122] Unfortunately, even if this should be proved, little can be done to prevent the accumulation of toxin in wild fish. TTX, though unlike STX chemically (Figure 54–6), is also a Na+ channel blocker and has an equally high toxicity for humans (2 mg may be lethal) and unfortunately continues to claim victims in Japan and elsewhere.[88,138]

Characteristics of the Disease. This disease is reported mostly from Japan and, less frequently, other Southeast Asian countries;[73,132] however, it also has been reported from the US.[46] The symptoms of puffer fish poisoning are similar to those from PSP and, though quite different chemically, the two classes of toxin act in the same way to block transmission of Na^+ ion in nerve cells. Onset is rapid (within minutes of consumption of toxic flesh), with tingling of lips, tongue, and fingers leading to paresthesis of extremities. Nausea and vomiting are also early symptoms. In severe cases, there is progressive paralysis, and the patient may die from asphyxiation due to respiratory paralysis. Severity of the disease is dependent on the dose of TTX absorbed. Dose levels are remarkably similar to those for PSP, with 1 to 4 mg being lethal. Treatment is supportive with gastric lavage and respiratory assistance the principal recommended actions.[134] The disease causes a variable number of cases in Japan each year where the toxic species of puffer (or fugu) are considered a delicacy. The fish are prepared and served in special restaurants by specifically trained fugu cooks who seek to present only the portions of the fish with no or minimal toxin; nevertheless, each year consumers of Fugu become sick and some die.[88] There is confusion among some fishermen and consumers regarding which puffers are toxic or when potentially toxic species become toxic. Even in the US the Northern Puffer (*Sphoeroides*) was declared a nontoxic species in an article published in 1988 despite the fact that seven cases, including three fatalities, were reported in Florida between 1951 and 1974.[46] The common puffer fish, *Arothron hispidus*, has been implicated in at least seven fatalities in Hawaii in recent years, and outbreaks still occur in other Pacific countries.[141] It has been reported that puffer fish raised by culture are nontoxic,[103] which raises prospects for a safe fugu product. Similarly, an understanding of the role of bacteria in producing the toxin particularly in view of the observations by Gallagher and Birkbeck[30] concerning metabolic control of tetrodotoxin production could be used to modify aquaculture procedures to ensure toxin-free fish. However, it is difficult to see how this knowledge could affect the safety of ocean-caught fish, and wild puffer fish must be assumed to represent a high risk of illness and death for the uninformed consumer.

Food Vehicles and Transmission to the Consumer. Though TTX has been found in a range of marine and other animals, the risk to consumers seems to be mainly from puffer fish. Different species of puffer fish vary in their toxicity. Particularly toxic species include *Fugu niphobles*, *F. poecilonotum*, *F. vermiculare*, and *F. pardale.*[79] The dangers of eating such fish are generally well recognized by fish eaters and regulators in Japan and other countries in Southeast Asia and some degree of risk



ANHYDROTETRODOTOXIN

is accepted by fugu eaters to achieve the "fugu experience."[73,134] There is little risk to the general fish-eating public because the toxic puffer fish species are not widely marketed.

Detection and Control. Control of puffer fish poisoning requires strict surveillance of fish destined for fugu establishments, and now in several countries (eg, Japan and the US), the authorities require assurance that the fish is nontoxic. This requires regular toxin testing traditionally done by a mouse assay using similar procedures to those described for PSP. There is a high fatality rate associated with puffer fish poisoning, and this is reflected by rapid death of test mice. One MU is the amount of TTX that will kill a male mouse of the Japanese ddY strain weighing 20 g in 30 minutes and is equivalent to 220 ng TTX: it has been estimated that 10,000 MU cause death in a human.[79] A fluorometric TTX analyzer has been developed in Japan.[138] This system uses extracts prepared by boiling fish tissues with .02 N acetic acid and passing the centrifuged, membrane-filtered (<10,000), suitably cooled and diluted extract through *LC* column to separate TTX and its congeners. The column is eluted with heptafluorobutyric acid and heated with NaOH and read in a fluorometer. The method has a minimum detection level of 5 ng per injection and is simple and effective for routine monitoring.

Obviously, the mouse neuroblastoma cell method described for STX testing works equally well as an assay for TTX because both toxins are detected by their Na^+ channel-blocking effect, which antagonizes the effects of ouabain and veratridine on the cells. It is slower than the mouse test but provides a simple alternative to animal testing.[69,70] Other methods, including immunoassays, thin layer and high-performance chromatography, gas chromatography, mass spectroscopy, and nuclear magnetic resonance spectroscopy have been proposed and tested.[138]

54.4 CONCLUDING REMARKS

In recent years, there has been an increase in the incidence of human disease from fish and shellfish poisoning. This is well documented in the case of the US,[46] Europe,[21] Indo-Pacific,[25,67] and New Zealand.[65,66] The increase of disease has been associated with the appearance of two new shellfish poisonings—DSP and ASP—and one fish poisoning newly recognized to be important—Scombroid poisoning—the recognition of dozens of new species of toxigenic microalgae, and an apparent widespread dispersal or emergence of such algae in coastal waters around the world.[36,115,118] The relationship between human poisonings and the occurrence of toxigenic microalgae is clear, and most of the increase of disease incidence probably is due to the spread of these algae. However, other contributing factors are expanding tourism in tropical coastal areas and islands, growing imports of fish and shellfish from warm-water fisheries into North America and Europe, and improving recognition of seafood poisoning by physicians and other health professionals. Expanding tourism and growing imports have the same effect of exposing uninformed consumers to these products, while better diagnosis of these illnesses could inflate the statistics by revealing previously unrecognized cases. It should be noted that the population at risk from imports or tourism is no more susceptible to becoming ill from consumption of toxic fish or shellfish than the informed local inhabitant who eats such seafood since no immunity is conferred by previous experience; it is a matter of informed choice.

The reasons for the development of the prime cause of seafood poisoning increase are still in dispute. The spread of toxic dinoflagellates and other microalgae could be due, in part at least, to direct transport of the organisms by human action, such as in ship's ballast or incidental to direct transfer of aquatic species. In some situations, spread can be ascribed to changing ocean conditions due to naturally cyclic events (eg, El Niño phenomenon, global warming) or human alteration of habitat (eg, destruction of reefs) or pollution. The appearance of new toxigenic microorganisms is more difficult to understand. They may in fact simply have gone unobserved before because they were not actively looked for. There may be some credibility for this explanation in the case of DSP because the symptoms could be ascribed easily to an unknown bacterium, but given the extensive scale of outbreaks of DSP, particularly in Europe where scientists abound, this seems unlikely. Another explanation is that there has been an increase in toxicity within the incriminated toxigenic group, possibly by mutation. Identification of the microorganisms associated with toxification of fish and shellfish and mapping of their occurrence in world oceans is easily being actively pursued with some success, partly as a result of the application of methodologies derived from molecular biology including biochemical markers and RNA and DNA probes.[4,108] At least 57 species of toxic phytoplankton[118] and numerous species of toxigenic bacteria[29,127] have been reported.

The information derived from recent studies certainly has enhanced understanding of the origins and distribution of toxins through the marine ecosystem, but also has revealed that toxins rarely occur in a single chemical form and that they undergo change as they pass through the food chain.[12,15,62] This complicates the assay of toxicity in seafoods by chemical methods because different forms of a toxin show different potency. Another analytical problem now recognized is the concurrent presence of toxins from different species of toxigenic microorganisms in shellfish or fish: examples include PSP and DSP toxins in mussels,[72] palyotoxin and ciguatoxin in mackerel,[54] and possibly OA and ciguatoxin in "ciguateric" fish. Of course, the existence of such mixtures, if they really occur, raises problems for symptom definition of the disease in human patients.

The future pattern of occurrence of human seafood poisoning is difficult to predict. The ocean is a very large place (70% of the world surface is covered by water) and the current pace of discovery of toxic microalgae suggests there are more to be found; however, for shellfish poisoning at least there are grounds for hope. First, because there is a worldwide effort in coastal areas to identify toxic algae that successfully is outpacing human outbreaks, and second because countries increasingly are installing early warning procedures based on a combination of coastal phytoplankton surveys and toxin testing of edible shellfish. Under the best of circumstances, given such a system, the first large outbreak of shellfish poisoning should be the last because it would provide the necessary information to prevent future outbreaks.

Prevention of disease depends on intercepting toxic fish before they enter the food marketing system. This may require complete prohibition of landings of fish species with a high probability of toxicity or placing a burden of proof concerning nontoxicity on individuals or companies marketing such fish. Batch testing of fish is feasible for some toxins in particular situations, such as histamine testing of potentially scombrotoxic tuna and mahi mahi. Testing of individual fish already is enforced for puffer fish in Japan and the US, but may not be elsewhere in Southeast Asia. The problem is particularly difficult in the case of ciguatera because of the large number of species involved, the potential severity of the disease, and the widespread involvement of ciguateric species in subsistence fisheries. The latter is particularly difficult because fishermen have few other options to maintain their families, and it is well known that toxic levels can fluctuate widely in individual fish. In this case, as well as in more commercial situations, the need for an inexpensive test that can be applied at the point of capture is great.

It is encouraging that some progress has been made in the treatment of seafood poisonings, particularly with the apparent success of intravenous mannitol for ciguatera.[90] An unexpected but exciting development is the reported effectiveness of a monoclonal antibody for prophylaxis and treatment of tetrodotoxin poisoning in mice[98] because antigenic potential has been poor for seafood toxins in general. More research is needed into useful treatments to ameliorate the effects of fish and shellfish poisoning on the patient particularly because some of the toxins involved have been shown to be potentially carcinogenic.

55.1 INTRODUCTION

It has been estimated that 5 to 35 of every 100 individuals in developed countries are affected by gastroenteritis each year and a large proportion of those infections are due to foodborne pathogens.[15] According to Archer and Young,[8] on the average, every United States (US) citizen suffers at least one episode of diarrhea annually. Most cases of diarrhea incurred by ingestion of a foodborne pathogen are mild, self-limiting, and of short duration. However, they should not be dismissed lightly because diarrheal episodes may have far-reaching effects that can be physically, psychologically, and economically catastrophic and may even result in death. The elderly and the young generally are more susceptible to foodborne diseases. In the US, the number of children less than 5 years of age has increased from 17.2 million in 1970 to 18.8 million in 1992, and the number of individuals more than 75 years of age has risen from 7.5 million to 13.8 million.[198] Projections in population growth show increases in the elderly population and in the number of children < 5 of approximately 100% and 15%, respectively, by the year 2025. Other developed countries probably will have similar statistics. Thus an ever-increasing, less immunocompetent population will be at risk for the consequences of foodborne diseases. In this chapter, we discuss some of the complications and long-term consequences that humans may experience from gastrointestinal insults due to foodborne pathogens.

55.2 REACTIVE ARTHRITIS AND REITER'S SYNDROME

55.2.1 The Diseases

The reactive arthritides (or seronegative spondyloarthropathies) include those arthritic syndromes characterized by sterile inflammation of the joints. These syndromes include reactive arthritis, Reiter's syndrome, and ankylosing spondylitis. The spondyloarthropathies characteristically involve the sacroiliac and peripheral joints and are seronegative for rheumatoid factor.[25] Other pathological features may include changes in the eyes with potential vision loss, the urinary tract, aortic valve, lung parenchyma, and skin, as well as changes at the sites of ligamentous insertion into bone. Importantly, the genetic makeup of certain individuals renders them more susceptible to the reactive arthritides.[25]

Gastrointestinal or genitourinary infections may trigger reactive arthritis or Reiter's syndrome.[3,214] Ebringer[44] has stated that ankylosing spondylitis follows *Klebsiella* infections, but Calin[25] and Russell and Almazor[146] disagree that there is a close relationship between arthritis and *Klebsiella* or other microorganisms. There is no compelling evidence that anklylosing spondylitis is a postenteric or postvenereal arthritis.

One to two weeks after an enteric or venereal infection, the patient with reactive arthritis presents with arthritis of several joints, generally those of the lower extremities—the knees and metatarsophalangeal (ball of the foot) joints. The arthritis usually is asymmetrical. Other symptoms may include back pain and inflammation at ligament-bone junctions (swelling of fingers and toes ["sausage digits"] and/or pain and tenderness beneath heels). The most common extra-articular manifestation in reactive arthritis is heaped-up scaling lesions present on the palms and soles (keratoderma blennorrhagica) and lesions on the buccal and pharyngeal mucosa, palate, and tongue. Conjunctivitis is present in approximately 30% of the patients, and a small number (< 5%) may have anterior uveitis (inflammation of iris, ciliary body, and choroid); cardiac involvement and urethritis may also occur. Ulcers of the glans penis (circinate balanitis) may be present in approximately 30% of patients with postvenereal reactive arthritis but are rare in patients with postenteric disease.[3,47,49]

Reiter's syndrome is a subtype of reactive arthritis and is characterized by a triad of symptoms: arthritis, conjunctivitis, and urethritis, which may occur together or sequentially. If one or more of these symptoms is absent, the term incomplete Reiter's syndrome is used.[3,47] Arthritis appears 2 to 6 weeks after the triggering infection; it is asymmetric and affects mainly the knees and ankles. Sausage digits, swelling at the insertion of the Achilles tendon, plantar fascitis (inflammation of the fibrous connective tissue in the sole of the foot), and low back pain are typical symptoms of Reiter's syndrome. Urethritis is manifested by dysuria and a thin, watery discharge; prostatitis and cystitis (inflammation of bladder) may be present. The conjunctivitis of Reiter's syndrome usually is mild; however, more severe complications such as iritis (inflammation of iris), uveitis, and corneal ulceration may develop. Other symptoms such as keratoderma blennorrhagica, ulcers of the glans penis, and oral lesions may be seen. Cardiac or neurological symptoms may be additional complications in some patients.[85,214] The clinical and pathological features of reactive arthritis and Reiter's syndrome often overlap.

The average duration of reactive arthritis or Reiter's syndrome is less than 6 months; however, some patients may show symptoms for more than 12 months.[85,100] For example, in a study of 25 patients with *Chlamydia*-induced reactive arthritis and 27 with arthritis triggered by enterobacteria, 10 of the *Chlamydia*-induced arthritis patients and 5 of those with enterobacteria-induced arthritis still showed clinical signs of arthritis after 1 year.[57] However, after 2 years, none of the *Chlamydia*-induced arthritic patients showed clinical symptoms and only one of the enterobacteria-induced arthritic patients was symptomatic. In a study of post-*Salmonella* reactive arthritis following a large food poisoning outbreak, Thomson et al.[190] found that chronic symptoms persisted for at least 5 years in a majority of the arthritic patients. The studies of Glennas et al.[57] and Thomson et al.[190] clearly indicate that the effects of foodborne enteritis may be long lasting in certain individuals.

Nonsteroidal anti-inflammatory drugs, intra-articular injections of steroids, and physical therapy are the treatments recommended for reactive arthritis. Antibiotic treatment in arthritis triggered by enteric pathogens does not appear to be effective in shortening the duration of the arthritis; however, use of antibiotics with chlamydial infections probably reduces the risk of postvenereal reactive arthritis.[100,175]

55.2.2 Role of HLA-B27 Antigen in the Diseases

There is a genetic predisposition for the reactive arthritides. Possession of the major histocompatibility complex (MHC) gene for the Class I antigen, HLA-B27, may predispose individuals infected with one of the triggering organisms to either reactive arthritis or Reiter's syndrome.[85] HLA antigens that cross react with HLA-B27, such as HLA-B7, also are associated with an increased risk for arthritis.[215] The frequency of the HLA-B27 allele in different populations varies; less than 1% of Japanese, 2% to 4% of American Blacks, and 6% to 10% of Caucasians are positive. The allele is absent in African Blacks and Australian aborigines.[30,127] Arthritis develops in approximately 2% of individuals (both HLA-B27 negative and positive) infected by a triggering organism, whereas approximately 20% of infected individuals that possess the HLA-B27 allotype will develop arthritis.[3] In a patient population suffering from reactive arthritides, 60% to 80% were HLA-B27+.[85]

Molecular mimicry generally is invoked to explain the association between possession of the HLA-B27 antigen and increased susceptibility to reactive arthritis. Infection might lead to formation of antibodies that cross react with region(s) of the HLA-B27 molecule having structural similarity to antigens of the triggering bacterium, thus resulting in autoimmunity.[54] Indeed, antisera from arthritic patients react with peptides from the HLA-B27 antigen;[54] however, the molecular mimicry theory does not explain the tissue specificity of the reactive arthritides. HLA-B27 is a Class I antigen of the MHC and is found in most somatic cells of the body, yet the pathology of the diseases is limited to a few tissues. In addition, bacteria not known to cause one of the reactive arthritides may also induce the generation of antibodies that cross react with peptides of the HLA-B27 molecule.[87] To further complicate matters, disease is not limited to HLA-B27+ individuals and most HLA-B27+ patients infected with a triggering organism do not develop arthritis. Thus, at present, it is unclear why HLA-B27+ individuals have an increased susceptibility to the reactive arthritides.

55.2.3 Microorganisms That Induce the Diseases

Microorganisms that trigger the reactive arthritides cause infections at mucosal surfaces, have lipopolysaccharides (LPS) on their outer membranes, and are intracellular pathogens.[112] The reactive arthritides are sterile arthritides that originate from infections at nonarticular sites. Immunohistological data of intestinal biopsy specimens of patients with reactive arthritides demonstrated the presence of *Yersinia enterocolitica* bacilli in mucosal, submucosal, and lymphoid tissue. Generally, *Y. enterocolitica* were not culturable in biopsied material.[36] Viable microorganisms are not isolated from the joints; however, microbial antigens are present.[112,193] A number of gastroenteritis-producing bacteria have been shown to induce the reactive arthritides. These include *Campylobacter jejuni*,[134] *Salmonella enteritidis*,[106,189] *S. typhimurium*,[76] *Shigella flexneri*,[60] *S. sonnei*,[96] *Yersinia enterocolitica*,[94] and *Y. pseudotuberculosis*.[99] Although *S. enteritidis* and *S. typhimurium* are the most common *Salmonella* serotypes that trigger arthritis, other serotypes such as *S. agona*, *S. montevideo*, and *S. saint paul* have been implicated.[111] The venereal pathogen, *Chlamydia trachomatis*, is the major cause of sexually acquired reactive arthritides.[85] Other organisms that have been implicated as triggers of reactive arthritides include *Borrelia burgdorferi*, *Chlamydia pneumoniae*, *Clostridium difficile*, *Giardia lamblia*, *Vibrio parahaemolyticus*, and *Ureaplasma*.[29,158,159,175,179] Vaccinations also appear to be capable of triggering reactive arthritis. A vaccine containing heat-killed *S. typhi* and a vaccine against hepatitis B virus have been linked to the induction of reactive arthritides.[67,112]

55.2.4 Microbial Determinants That May Be Involved in Induction of the Diseases

An important feature of reactive arthritides is that viable microorganisms are not present in the joints; however, bacterial antigens are detected. LPS from arthritis-causing *S. enteritidis*, *S. typhimurium*, *S. flexneri*, and *Y. enterocolitica* have been found in synovial cells (polymorphonuclear leukocytes and mononuclear phagocytes) of arthritic joints.[58-60] It is probable that after infection with the triggering organisms, bacterial LPS and other antigens are transferred from the site of infection to the joints via phagocytic cells.[55,193]

The pathology of the reactive arthritides is due to cell-mediated immune responses, ie, the diseases are T-cell mediated.[195] T cells isolated from the joints of reactive arthritis patients proliferated *in vitro* (incorporated radioisotope) to the greatest extent when they were exposed to the specific organism such as *Chlamydia*, *Campylobacter*, *Salmonella*, or *Yersinia* that triggered the arthritis.[56] A cationic 19-kDa antigen, a β-subunit of *Yersinia* urease, is a target antigen for synovial T cells isolated from patients with *Yersinia*-induced reactive arthritis and is arthritogenic in rats.[137,166] The cationic antigen may interact with negatively charged cartilage proteoglycan, which would allow the antigen to be retained in the joint as a persistent source of immune stimulus.[55,137] Other antigens that have been identified as targets of synovial T-cell response include a cationic 18-kDa chlamydial histone-like protein[55] and a 14-kDa 50s subunit of the ribosomal R2 protein from *Yersinia*.[195]

Heat shock proteins (HSPs) may be arthritogenic proteins targeted by synovial T cells.[55,154] The stress proteins are highly conserved with a great deal of amino acid homology in HSPs from different species.[136,154] Pathogens produce HSPs during invasion of a mammalian host, and these proteins serve to protect bacteria from host defense mechanisms.

Similarly, host cells synthesize homologous proteins in response to the stress of bacterial invasion. If bacterial HSPs become targets for T cells, it is possible for the host homologues to cross react immunologically, thus resulting in autoimmunity.[136,154] Hermann et al.[69] isolated a *Yersinia*-reactive T-cell clone from synovial fluid of a patient with Reiter's syndrome, which proliferated *in vitro* in the presence of *Yersinia* antigens and human 65-kDa HSP. However, Probst et al.[138] were not able to isolate T-cell clones from reactive arthritis patients that reacted with purified *Yersinia* 61-kDa HSP, the homologue of the human 65-kDa HSP used by Hermann et al.[69] At present, insufficient data are available to indicate whether cross-reactions between homologous HSPs from humans and bacteria play a role in the reactive arthritides.

Synovial T cells from patients with *Yersinia-*, *Salmonella-*, or *Chlamydia*-induced reactive arthritis show a limited spectrum of cytokine production; the major cytokines found were interferon-γ (IFN-γ) and interleukin-2 (IL-2). The cytokines IL-4, -5, and -10 were not produced.[68,93,151] Lahesmaa et al.[93] have suggested that the cytokines produced by helper T cells type 1 (Th1 cells) may be important in the generation and propagation of joint inflammation. Th1 cells produce IL-2 and IFN-γ and are involved in cell-mediated responses, such as delayed-type hypersensitivity. IFN-γ and IL-2 stimulate the activity of cytotoxic T-cells, macrophages, and natural killer cells.[132] The IL-4, -5, and -10 pattern of cytokine production is found in Th2 cells. The Th2 cell cytokines are involved in humoral-mediated immunity and assist in antibody production by inducing B-cell differentiation and expansion. The cytokines are also involved in promoting allergic type responses.[132] Cross-regulation of the subsets occurs because IFN-γ can inhibit cytokine production by Th2 cells. IL-4 and IL-10, produced by Th2 cells, can suppress (down-regulate) Th1 responses.[132]

While Lahesmaa et al.[93] proposed that the cytokine products of Th1 cells play a role in the pathology of reactive arthritis, Schlaak et al.[151] demonstrated that Th1 cells actually may prevent arthritis. Th1 cells control the intracellular replication of *Yersinia enterocolitica* in phagocytic cells. IFN-γ promoted intracellular killing of *Yersinia* by activating cytotoxic cells whereas IL-4 (produced by Th2 cells) antagonized IFN-γ activation. In addition, the Th2 cytokine, IL-10, inhibited the *in vitro* proliferation of *Yersinia*-specific T-cells and down-regulated production of IFN-γ and IL-2.[151] Thus, the data of Schlaak et al.[151] indicated that Th1 cell production of IFN-γ promotes the destruction and elimination of intracellular *Y. enterocolitica*. Therefore, it is probable that the pathology of the reactive arthritides is not due to excessive Th1 cell expansion *per se* but rather is due to an imbalance of Th1 and Th2 cell activities.

Arthritogenic pathogens may produce proteins that behave as superantigens and stimulate T-cells. Stuart and Woodward[174] have demonstrated an antigen in *Y. enterocolitica* that behaved as a T-cell superantigen and a superantigen from *Y. pseudotuberculosis* has been isolated, purified, and partially sequenced.[2,197,213] Nothing is known concerning superantigen activity in other microorganisms that induce reactive arthritides. Superantigens can stimulate proliferation of a large number of T cells bearing a particular variable region of the β chain (Vβ sequence) of the T-cell receptor. Each superantigen will recognize one to five different Vβ sequences. As many as 5% to 25% of T cells having the proper Vβ sequences may be activated by a superantigen, whereas a conventional antigen may engage only about 0.01% of the T-cell pool. The result of such massive T-cell stimulation is substantial cytokine release, including IL-2, -4, and -6, tumor necrosis factors, and IFN-γ.[75,152,164,183,222]

Lahesmaa et al.[92] visualized the role of bacterial superantigens in the reactive arthritides in the following manner: inflammation of the joint may result from massive cytokine production due to superantigen stimulation of large numbers of T cells. Alternatively, the superantigen could contribute to inflammatory synovitis by expanding a population of autoreactive T cells that recognize a particular synovial antigen, but a role of superantigens in the pathology of the reactive arthritides is purely speculative at the present time.

Bacterial LPS are present in synovial fluid cells,[58-60] but are not considered arthritogenic antigens because LPS do not activate T cells.[68] The outer-membrane proteins (OMPs), YadA and YopH, of *Y. enterocolitica* may contribute to arthritogenicity in rats because mutant strains lacking the ability to produce these OMPs demonstrated decreased arthritis-inducing ability.[53,63] YadA binds to extracellular matrix proteins such as collagen, laminin, and fibronectin present in joints.[48,62,155,156,178,185] A *Y. enterocolitica* strain lacking the chromosomal gene that encodes the iron-chelator, yersiniabactin, did not induce arthritis in rats.[53] It is not known whether the *Y. enterocolitica* OMPs or yersiniabactin play a role in the induction of the reactive arthritides in humans.

It appears that the response of synovial T cells to antigens of the arthritis-triggering microorganism plays an important part in the pathogenesis of the reactive arthritides; however, it is unclear which bacterial antigen or antigens are arthritogenic and activate T cells. Recent reviews have discussed the relationship between foodborne pathogens and the reactive arthritides[167,169] and the immunology of these disorders.[23]

55.3 GUILLAIN-BARRÉ SYNDROME

55.3.1 The Disease

The Guillain-Barré syndrome (GBS; acute inflammatory polyneuropathy) is a demyelinating disease of the peripheral nerves. Since the suppression of polio, GBS is now the most common cause of paralysis in developed countries.[143] In the US, the annual incidence of the disease is 1 to 2 cases per 100,000 people. Approximately two thirds of the cases follow an antecedent event such as bacterial or viral infection, surgery, immunization, or drug treatment.[143] Unlike the reactive arthritides, GBS does not have a familial association.[170]

Acute GBS begins with abnormal sensations and loss of touch in toes and fingers followed by difficulty walking and climbing stairs due to leg weakness. Weakness ascends from lower limbs to involve the trunk, upper limbs, and cranial nerves. Pain may be present in neck, shoulder, and back regions. Some patients have weakness of the facial and oropharyngeal muscles, and approximately 25% of patients have involvement of the respiratory muscles; a few of these patients may need assisted ventilation. There may be dysfunction in other organs enervated by the autonomic nerves (such as the heart and gastrointestinal and urinary tracts). The brain and spinal cord are not affected. Due to general paralysis, the patient usually is bedridden.[119,133,139,143,170,221] Within 3 to 12 months, most patients recover completely or are left with only minor abnormalities that do not interfere with a normal lifestyle; however, 10% to 20% of GBS patients have significant residual weakness that prevents resumption of prior occupation or lifestyle. Death occurs in 1.5% to 8.0% of the patients.[119,139,143,170] Death may be due to nosocomial (hospital-acquired) infections, respiratory distress syndrome, pulmonary emboli (blood clots), or cardiovascular complications.

In GBS, inflammatory lesions are scattered throughout the peripheral nervous system but are not present in the central nervous system. These lesions are characterized by invasion of the myelin sheath by macrophages, which strip myelin from intact axons. Axonal loss may also occur.[119,143,188] Both humoral and cellular immune mechanisms appear to be involved in GBS. Antiperipheral-nerve myelin antibodies are found in GBS patients and are highest when neurological symptoms appear; declining antibody titers against peripheral-nerve myelin correlate with clinical improvement.[90,206] These antiperipheral-nerve myelin antibodies exert their demyelinating action through complement activation. In addition, at least one fourth of GBS patients exhibit high levels of antibodies to the GM_1, GM_2, and GD_{1b} gangliosides.[211] Complement fixation and inflammation of neural tissue by antiganglioside antibodies may induce the pathology seen in GBS patients.

T-cell responses to peripheral nerve proteins are also involved in the pathogenesis of GBS.[86] There is proliferation of T cells and increased levels of soluble interleukin-2 receptors (sIL-2 R) in GBS. Increased serum concentrations of sIL-2 R indicate the presence of circulating activated T cells, which may be relevant to GBS pathogenesis.[65] Activated T cells may assist B cells in the production of antibodies against myelin components and may regulate, recruit, and activate macrophages that attack the myelin sheath.[33,65] In a later study, Hartung et al.[66] actually demonstrated that the cytokine interleukin-2 was markedly increased in GBS patients, and as patients recovered from the disease the level of the cytokine returned to normal, suggesting that interleukin-2 has a pathogenic role in GBS. The concentration of the cytokine, tumor necrosis factor-α, was increased significantly in approximately 25% of GBS patients, suggesting that this cytokine also may play a role in the pathogenesis of the disease.[46] Honavar et al.[71] suggested that the T-cell response may be the major cause of demyelination in some GBS patients, whereas antibody-mediated demyelination may be more important in other patients. T-cell and B-cell responses generally act in concert, and the different pathologies seen in GBS probably reflect the relative contribution of each cell type.[71]

Plasmapheresis (plasma exchange) or administration of intravenous immune globulin, if used early, can alleviate the effects of GBS.[40,191,200,201] The benefits of plasmapheresis probably result from the removal of harmful antibodies such as demyelinating antibodies.[191] It is not clear why intravenous immunoglobulin is effective. The use of plasmapheresis requires sophisticated equipment and trained personnel, whereas intravenous immunoglobulin treatment is less complicated. Although plasmapheresis and intravenous immunoglobulin aid in the recovery of GBS patients, supportive care and rehabilitation of the patient are of primary importance.[39] Recovery is slow, requiring several weeks to months. Many GBS patients require extended and scrupulous intensive care including positive-pressure ventilation in cases with respiratory failure, nutritional support via nasogastric tube feeding, prevention of pressure on peripheral nerves, and prevention of nosocomial infections. Most patients need physical and occupational therapy as well as strong psychological support.[144,170]

55.3.2 Variants of Guillain-Barré Syndrome

Miller-Fisher syndrome (MFS) is an acute, self-limiting neuropathic disorder characterized by ophthalmoplegia (paralysis of eye muscle), ataxia (muscle incoordination), arcflexia (absence of reflexes), and facial weakness. This variant accounts for approximately 5% of GBS cases and, except for ophthalmoplegia, the clinical features overlap with GBS.[141] Antibodies to GQ_{1b} ganglioside are present in most cases of MFS.[212,218] Roberts et al.[141] presented evidence suggesting that a factor in sera of MFS patients, probably the anti-GQ_{1b} antibody, is responsible for muscle weakness. As in the case of GBS, plasmapheresis or intravenous serum globulin treatment aids in recovery of patients with MFS.[171,217]

Chinese paralytic syndrome (CPS; also known as acute motor axonal neuropathy) is easily confused with GBS; CPS differs from GBS in that the disease has a summer seasonality, usually involves children, and occurs predominantly in rural areas of northern China.[117,118] CPS cannot be distinguished from GBS clinically but the disorders are distinguishable by electrodiagnosis. In CPS, there is little evidence of demyelination; the disorder may result from a lesion in a reversible distal motor nerve terminal or anterior horn cell.[117,118] As in GBS, high titers of IgG anti-GM_1 are present in patients with CPS.[89] Cases similar to CPS have been reported elsewhere in the world, and the disease is probably not limited to China.[117]

55.3.3 Microorganisms That Induce the Disease

There have been a few reports of infection with *Borrelia burgdorferi*, *Mycoplasma pneumoniae*, and *Salmonella typhi* before the appearance of GBS,[64,73,147] but infections by *Campylobacter jejuni* are the major bacterial cause of GBS.[120,139] In the US, 20% to 40% of GBS cases show evidence of recent *C. jejuni* infection. The annual incidence of *C. jejuni* infection prior to the appearance of GBS has been estimated to range from 0.17 to 0.51 cases per 100,000 people.[120] MFS and CPS also have been associated with *C. jejuni* infections.[21,216]

55.3.4 Microbial Determinants That May Be Involved in Induction of the Disease

GBS may be induced by infection with *C. jejuni* if an immune cross-reaction between peripheral nerve antigens and bacterial antigens occurs. Antibodies to neural gangliosides have been found in sera from 231 of 847 (27.3%) GBS patients; the most common antibody is directed against the ganglioside, GM_1.[211] GBS patients with antibodies that react with GB_1 or GD_{1b} gangliosides also show a higher incidence of prior *Campylobacter* infections than other GBS patients.[204,209] *C. jejuni* LPS isolated from strains associated with GBS have regions homologous to the human gangliosides GM_1 and GD_{1b}.[12,13,219] Patients with MFS show high antibody levels against the ganglioside GQ_{1b}.[212,217] Yuki et al.[220] demonstrated that the GQ_{1b} epitope was present on LPS from *C. jejuni* strains isolated from patients with MFS. Molecular mimicry between homologous regions of the bacterial LPS and the peripheral-nerve gangliosides may lead to autoimmunity and GBS or MFS.

Campylobacter jejuni toxin binds to GM_1; this toxin-GM_1 complex could alter recognition of self antigens and thus trigger the production of antibodies directed against neural antigens.[139] There are no data, however, supporting the role of the toxin in induction of GBS. Fujimoto and Amako[52] found that antisera from patients with *C. jejuni*-induced GBS reacted with the myelin proteins P0 and P2. Antibacterial antibodies that cross react with myelin proteins may lead to an autoimmune reaction with resultant GBS. Rees et al.[139] suggested that *C. jejuni* may induce GBS via superantigens. The superantigen could activate large numbers of antimyelin or antineural T cells resulting in the production of high levels of cytokines, which could damage nerve tissue and induce GBS; however, there is no evidence that *Campylobacter* species synthesize superantigens.

There is evidence, therefore, of homology between components of *C. jejuni* and antigens in peripheral-nerve gangliosides and in myelin proteins. It is possible that immune reactions against *C. jejuni* antigens may induce GBS and MFS. Smith[168] has reviewed the role of *C. jejuni* in the induction of GBS and related diseases.

55.4 HEMOLYTIC UREMIC SYNDROME

55.4.1 The Disease

Hemolytic uremic syndrome (HUS) is a triad of microangiopathic hemolytic anemia (disease in which small blood vessels become distorted, resulting in damage or destruction of red blood cells), thrombocytopenia (abnormally small number of platelets in the circulatory system), and acute renal failure. The incidence of HUS is highest in early childhood but may appear in all age groups; the syndrome is the major cause of renal failure in children in the US.[10] Thrombotic thrombocytopenic purpura (TTP) is similar to HUS in histopathology and clinical aspects; however, the syndrome usually occurs in adults, appears to affect women more than men, is rare in children and infants, and prominent signs include fever and central nervous system involvement. It is not certain whether TTP and HUS are separate entities or merely represent different clinical endpoints of a common pathological process.[10] Remuzzi et al.[140] suggested that HUS and TTP are different clinical expressions of the same disease; renal failure is the prominent feature in children (HUS), whereas neurological involvement is the main feature in adults (TTP). However, Neild[124] stated that approximately 50% of patients with diarrhea-associated HUS have fever and that neurological involvement is common; thus, the distinguishing differences between HUS and TTP may be blurred.

Typical HUS is diarrhea-associated, with the enteric pathogen *Escherichia coli* O157:H7 as the main identified cause in the US, while atypical HUS is not preceded by nor associated with diarrhea. Atypical HUS has been associated with pregnancy, transplantation, malignancy, and use of certain drugs such as cyclosporin A, mitomycin C (or other immunosuppressive drugs), antibiotics, or oral contraceptives.[81]

Endothelial cells are the primary sites of injury in HUS.[121] The main target organ is the kidney, but other tissues such as the gastrointestinal tract (small and large intestine, pancreas, and liver), cardiovascular system, and the central nervous system may also be affected.[124,162] The organ or organs affected show the same underlying pathology, ie, thrombosis of the microcirculatory system due to platelet adhesion and aggregation at the sites of endothelial injury.[124]

In symptomatic, Shiga-like toxin (SLT)-producing *E. coli* O157:H7 infections, there is a prodromal illness of crampy abdominal pain and self-limited fever. Within 1 to 2 days, nonbloody diarrhea develops and progresses to bloody diarrhea in about 90% of US cases.[182] Vomiting may occur at any time during the illness. Approximately 7 days after the initiation of diarrhea, 5% to 10% of the patients less than 10 years of age present with HUS. The syndrome probably results from vascular endothelial damage in renal tissue following absorption of SLT from the infected gut.[181,182] Narrowing of renal arterioles and glomerular capillaries due to endothelial cell swelling and deposition of fibrin and platelet aggregates lead to mechanical damage or fragmentation of red blood cells and platelets as they traverse occluded microvessels.[82,121,145] Because all of the circulating blood of the body passes through the kidneys every 4 to 5 minutes,[79] it is not surprising that the resulting red cell damage leads to anemia. Adherence of platelets to the injured capillary walls contributes to the formation of microthrombi with further narrowing of the lumen of the vessels and leads to thrombocytopenia. Occlusion of the capillaries of the glomeruli results in reduced glomerular filtration; complete blockage of the renal microvessels can lead to tubular and glomerular necrosis. Thus, the overall effect of HUS is renal dysfunction.[82,121] Blockage of the microcirculation of other organs of the body may occur also in HUS.[124,162]

In TTP, the mortality rate can be greater than 90% in untreated patients; however, the majority (up to 85%) of children with HUS recover spontaneously or need only supportive treatment.[35,123] In many cases, treatment may be limited to rehydration of the patient and psychological reassurance of both child and parents. Tarr[182] recommends no antibiotic treatment for *E. coli* O157:H7 infections because antibiotics may lyse intracolonic pathogens, causing release of SLTs. In addition, Tarr[182] does not advocate the use of antimotility agents or narcotics in *E. coli* O157:H7 infections. Although these medications alleviate intestinal pain, they delay clearance of the pathogen from the gut and permit further SLT production. In mild cases of diarrhea-induced HUS without anuria, Kaplan[80] recommended rehydration if required, maintenance of hemoglobin level (by red blood cell transfusions), control of hypertension, and psychological support. If anuria is present, dialysis in addition to the other supportive measures is recommended.[80] In some HUS patients, there may be gastrointestinal, cardiovascular, or neurological involvement in addition to renal involvement and appropriate corrective measures must be initiated on a case-by-case basis.[107,162] In some patients, death may occur or there may be long-term physiological and neurological deficits.[107,162]

Intensive plasma infusion with fresh frozen, platelet-poor plasma was recommended by Kaplan[80] as a treatment for TTP patients; however, Daniel[35] indicated that plasma exchange (with fresh frozen plasma as the replacement fluid) may be more efficacious than plasma infusion in TTP. It is not clear whether the beneficial results of plasma infusion or exchange are due to removal of harmful agents (exchange) or replacement of essential entities that have become depleted (both exchange and infusion).[35]

55.4.2 Role of Blood Group and HLA Antigens

Taylor et al.[184] suggested that the P blood group may play a role in diarrheic HUS because SLTs can bind to ceramide groups on the P blood group glycolipid antigens. Red blood cells (RBCs) from 80% to 95% of the normal population have the P1 blood group phenotype (comprising the P, P_1, and P^k antigens) and most of the remainder of the population have the P2 phenotype (P and P^k antigens but lacking the P_1 antigen). SLT-I and SLT-II bind to glycolipids containing terminal Gal-α(1→4)-Gal residues. The P^k antigen, which is Gb_3, globotriaosylceramide, and the P_1 antigen contain terminal Gal-α(1→4)-Gal residues. SLTs bound to RBCs with the P1 and P2 phenotypes but did not bind to RBCs of the p (P^{k-}, P^-, and P_1^-) phenotype.[20] SLTs showed reduced binding of RBCs deficient in the P^k antigen. There was a 10-fold decrease in binding of P2 phenotype RBCs by SLT-I and SLT-II compared with binding to P1 phenotype cells.[20] It was suggested that binding of SLTs to P1 phenotype RBCs is enhanced due to the presence of Gal-α(1→4)-Gal residues on both the P^k and P_1 antigens and that the P^k antigen may be less accessible to SLT binding on P2 phenotype RBCs than on P1 phenotype RBCs. Red blood cells do not synthesize protein and are resistant to the action of SLT. Taylor et al.[184] postulated that, by binding to red blood cells containing the P_1 antigen, SLT is rendered less available for toxic activity on nucleated endothelial cells.

Newburg et al.[126] and Taylor et al.[184] presented preliminary evidence indicating that the proportion of HUS patients with the P_1 antigen was significantly less than that of control patients and that the lack of P_1 antigen was more common in patients with severe HUS. These results suggest that the absence of the P_1 antigen is a risk factor for HUS; however, Robson et al.[142] found that HUS patients were as likely to have the P_1 antigen as were control patients. In these three studies,[126,142,184] the patient population was small, and it appears premature to draw any definitive conclusions concerning the role of P_1 blood group antigen in HUS.

Diarrheic HUS appears to show a greater incidence in children harboring the Class I HLA-B40 antigens.[160,199] These include HLA-B40, its splits (the closely related HLA-B60, -61, -41, -47), and the cross-reactive antigens -B44 and -B13. The number of patients studied was small (n = 89) and to evaluate properly the role of HLA-B40 antigens as risk factors for HUS, HLA typing of a large number of patients must be performed.

55.4.3 Microorganisms That Induce the Disease

Typical (epidemic or diarrhea-associated) HUS is a result of an infection with Shiga toxin-producing *Shigella dysenteriae* type 1 or SLT-producing enterohemorrhagic *E. coli* (EHEC). There is generally a prodrome of bloody diarrhea with *S. dysenteriae* or *E. coli* infections prior to HUS.[81] Reports from various parts of the world indicate that the most common cause of diarrhea-associated HUS is *E. coli* O157:H7. Marks and Roberts[114] have estimated that in the US, 3 to 8 individuals per 100,000 population acquire an *E. coli* O157:H7 infection each year. Five to ten percent of those infected individuals less than 10 years of age will develop HUS[125] and 4% to 13% of patients with diarrhea-associated HUS do not survive.[140] A recent estimate from the US Centers for Disease Control and Prevention indicated that there is an annual minimum of 20,000 cases of *E. coli* O157:H7 infection and 250 deaths.[26]

Other SLT-producing *E. coli* serotypes have also been implicated in HUS.[61,83] *E. coli* serotype O103:H2 was isolated from stools of 6 of 69 children with HUS in France between 1987 and 1989.[113] By colony blot hybridization using labeled DNA probes, Cordovéz et al.[31] found *E. coli* serogroups O157, O26, and O111 in the stools of children with HUS. All of the isolates hybridized with an EHEC plasmid probe and with either an SLT-I probe or probes for SLT-I and SLT-II. Most *E. coli* O157:H7 strains do not ferment sorbitol within 24 hours; therefore, differential media containing sorbitol are frequently used in clinical settings to screen bloody stools for the presence of the organism. However, looking only for *E. coli* O157:H7 using these media may lead to an underestimation of the number of cases of HUS caused by other SLT-producing serotypes.

More rarely, HUS may be a result of infection by neuraminidase-producing *Streptococcus pneumoniae*.[81,107] Other microorganisms, bacterial and viral, have been implicated in the causation of HUS but the reports concerning these organisms are anecdotal and their role in HUS is unsubstantiated.[81] However, one report described SLT-II-producing *Citrobacter freundii* as the causative agent of a nursery school outbreak of severe gastroenteritis and HUS in a small town in northwest Germany.[196]

The primary requirement for an agent to induce HUS is the ability to damage endothelial cells of the vascular system. Shiga toxin, SLT, neuraminidase, LPS, phospholipase C, mitomycin C, and cyclosporin A each have been shown to injure vascular endothelial cells.[81]

The incidence of TTP is approximately one per million population and therefore it is uncommon in comparison with HUS.[80] Cases of TTP resulting from infections by SLT-producing *E. coli* associated with a prodrome of bloody diarrhea have been reported;[10] however, Kaplan[80] stated that patients with "TTP" induced by SLT-producing *E. coli* probably had HUS rather than TTP. In Kaplan's view,[80] a definitive cause for TTP has not been established.

55.4.4 Microbial Determinants That May Be Involved in Induction of the Disease

Adherence and colonization are necessary first steps in induction of disease. One of the putative attachment factors for *E. coli* O157:H7 induces the attaching and effacing (A/E) cytoskeletal lesion. The histopathology of A/E is characterized by intimate bacterial attachment to intestinal epithelial cells, effacement of microvilli, rearrangement of the cellular cytoskeleton, and cupping of the cell membrane around the bacterium in a pedestal-like formation.[78] Microfilamentous actin (F-actin) accumulates beneath the cytoplasmic membrane of the host cells at sites where bacteria have attached. The *eaeA* gene necessary for expression of A/E in *E. coli* O157:H7 has been cloned and sequenced.[17] This gene is 97% homologous to the enteropathogenic *E. coli eaeA* gene over the first 2,200 base pairs (bp), and there is only 59% homology over the last 800 bp. Some *Citrobacter freundii* and *Hafnia alvei* strains also produce A/E lesions and possess DNA homologous to the *E. coli eaeA* gene.[51,150] There are also similarities between the sequence of the *eaeA* gene and that of the *Yersinia inv* (invasin) gene. The gene product of the enteropathogenic *E. coli eaeA* is a 94-kDa outer membrane protein, intimin, which is necessary but not sufficient to produce A/E lesions.[38] The EHEC *eaeA* gene protein product is 97 kDa and is termed intimin$_{O157}$.[109] The majority of SLT-producing *E. coli* strains (O157:H7 and other serotypes) causing disease in humans and cattle possess an *eae* gene.[108]

Other determinants as well as *eaeA* appear necessary for production of A/E.[42] A 35-kbp genetic locus designated LEE was found to consist of multiple regions involved in the formation of A/E lesions.[115] This locus is conserved among enteropathogenic *E. coli*, EHEC, and other organisms that have been shown to produce A/E lesions, such as *Hafnia alvei* and *Citrobacter freundii*, but was absent in nonpathogenic *E. coli* and in other non-A/E bacteria. The LEE region contains *eaeA*, *eaeB*, *sepA*, and *sepB* loci that encode determinants necessary for A/E lesion formation. The *selC* (selenocysteine) tRNA locus was shown to be the LEE insertion site on the *E. coli* chromosome.[115]

EHEC are not invasive when tested by the Sereny test;[186] nonetheless, strains of *E. coli* O157:H7 can invade certain human cell lines.[131] Invasion ability is encoded chromosomally and depends on short-lived invasion protein(s) produced by the bacteria and also on the presence of eukaryotic microfilaments. Use of cytochalasin D, a potent depolymerizer of microfilaments, inhibited internalization of the bacteria; however, invasion of enterocytes may not be necessary in induction of disease because the organism produces large amounts of SLT, which results in rapid cell death.[186]

Iron is necessary for the growth of microorganisms *in vitro* and *in vivo*; thus, iron-acquiring mechanisms can be considered as virulence factors in pathogens. Various serotypes of EHEC produce temperate bacteriophage or plasmid-coded hemolysins.[19,153] Beutin et al.[19] suggested that there may be a close relationship between enterohemolysins and SLT production because they found that 89% of EHEC strains produce both factors. Law and Kelly[97] found that 20 of 20 strains of SLT-producing O157 strains produced enterohemolysins and growth of all O157 strains was stimulated by the hemoglobin and heme released by action of the enzyme. However, only 22 of 33 SLT-producing non-O157 strains produced enterohemolysins; the growth of 7 of 33 strains was stimulated by heme, whereas growth of only 4 of 33 was stimulated by hemoglobin. Law and Kelly[97] suggested that the production of enterohemolysins and ability to use products of hemolysis may account for the greater incidence of bloody diarrhea and HUS seen with *E. coli* O157 than with non-O157 strains.

Iron in excess of that needed for bacterial growth depresses synthesis of Shiga toxin and SLT-I but not SLT-II or SLT-IIv (currently designated SLT-IIc).[104] The chromosomal gene *fur* regulates the temperate bacteriophage *slt* operon (genes necessary for expression of SLT). The *fur* gene product, the Fur protein, acts as a corepressor with Fe^{++}; the Fur-iron complex binds to the Fur-binding site of the *slt* gene promotor and prevents the transcription of SLT-I.[104] SLT-II and SLT-IIc genes do not contain sequences in their promotor regions for binding of the Fur repressor protein.

The toxins of the Shiga family appear to be the most important virulence determinants in hemorrhagic colitis and HUS.[163] The genes for Shiga toxin are located on the chromosome, whereas those for SLT-I and SLT-II are encoded by toxin-converting bacteriophages. The amino acid and DNA sequences of Shiga toxin and SLT-I are similar with greater than 99% genetic homology. The two toxins have similar biologic activities and cross-react immunologically.[172] SLT-I and SLT-II are different antigenically; however, they show cytotoxicity for the same cell lines and possess similar lethal and enterotoxic activities.[173] Amino acid and DNA sequence homologies between SLT-I and SLT-II are 56% and 58%, respectively.[77] Shiga toxin and the SLTs are subunit toxins consisting of an "active" A subunit and multiple "binding" B subunits. The B subunits bind to the receptor (Gb_3) on the mammalian cell surface; following internalization, the A subunit is cleaved into the A1 and A2 fragments. The A1 fragment disrupts protein synthesis by removing an adenine residue from the 28S rRNA component of the 60S ribosomal subunit and thereby blocks peptide elongation. Shiga toxin, SLT-I, and SLT-II block protein synthesis by the same mechanism.[70,83,128]

Human umbilical vascular endothelial cells (HUVEC) and human renal microvascular endothelial cells (HRMEC) are damaged by low levels of Shiga toxin.[129,130] Cell viability and protein synthesis of renal endothelial cells were reduced by 50% with Shiga toxin at levels of 1 pM, whereas more than 1 nM of Shiga toxin had no effect on umbilical endothelial cells. The Gb_3 level of renal endothelial cells was approximately 50 times that of umbilical cells.[130] Gb_3 is a major component of renal tissue; the Gb_3 level was higher in the renal cortex than in the medulla, which correlates with the location of lesions seen in HUS.[22] However, the Gb_3 level in infant kidney was considerably less than that in adult kidney, which does not correlate with the apparent increased susceptibility of children to HUS. Lingwood[103] studied the binding of fluorescein-conjugated SLT-1 to frozen human renal sections and found that SLT was detected in infant (< 2 years of age) glomeruli but not in adult. SLT-binding by infant glomeruli correlated with the observed incidence of diarrheic HUS in children. It appears that concentration of Gb_3 in renal tissue may not be the critical factor in HUS.

Impairment in the normal function of the renal fibrinolysis system may contribute to the pathology of HUS.[110] HUVEC and HRMEC differ in types and levels of fibrinolysis factors produced such as tissue-type and urokinase-type plasminogen activators and plasminogen activator inhibitor-1 (PAI-1). HUVEC are antifibrinolytic because expression of PAI-1, the prime inhibitor of fibrinolysis factors, is high, whereas HRMEC produce low amounts of PAI-1, and therefore are profibrinolytic. Incubation of the cells with Shiga toxin resulted in a greater reduction in total cellular protein synthesis and cell viability for HRMEC than for HUVEC, and the production of fibrinolysis factors was decreased to a greater extent than total protein synthesis in HRMEC.[110] Thus Shiga and Shiga-like toxins may effect a decrease in renal fibrinolytic activity, leading to thrombosis.

The role of the Shiga family of toxins in disease may be visualized as follows: the A1 fragment of the toxin disrupts protein synthesis by the endothelial cells of the intestinal vasculature leading to cell death and hemorrhagic colitis. With the breakdown of intestinal integrity, toxin enters the circulatory system and can locate in the kidneys and other organs and cause damage to vascular endothelial cells. Endothelial cell death in the renal vasculature (or vasculature of other organs) allows circulating blood to be exposed to the underlying collagen with initiation of coagulation. The resultant narrowing of the vessel lumens eventually leads to HUS or complications in other organs.[70,81,135]

A satisfactory explanation of the mechanism of SLT induction of HUS is hampered by the lack of suitable animal models. Animal models have been described, including a mouse model,[102,207,208] a gnotobiotic pig model,[41] and a rabbit model;[165] however, none of the models emulate completely the disease syndrome seen in human EHEC infections. Tarr[180] stated that the rabbit model of Sjogren et al.[165] holds promise as a small-animal model that may provide much-needed answers to the involvement of SLTs in HUS.

55.5 OTHER COMPLICATIONS AND LONG-TERM CONSEQUENCES OF FOODBORNE DISEASE

Immunologic phenomena involving autoimmune reactions with production of immune complexes or of antibodies against "self" antigens and immunologic responses to bacterial antigens and superantigens may result in complications following infection with enteric pathogens. Several of these complications are discussed.

55.5.1 Glomerulonephritis

Glomerulonephritis (acute/postinfectious) may develop after an infection with group A nephritogenic streptococcal strains (poststreptococcal glomerulonephritis) or following infections with other agents, including enteric pathogens. Postinfectious glomerulonephritis is usually associated with deposition of immune complexes within the glomerulus activating a cascade of events leading to tissue destruction. *Campylobacter jejuni* antigen was identified in the glomeruli of a 5-year-old child who had suffered from *C. jejuni* enteritis with bloody diarrhea several weeks earlier.[7] A *Shigella* virulence protein antigen was found in immune complexes isolated from the serum of a patient who had dysentery due to *S. flexneri* type 1B and who developed acute glomerulonephritis.[122] *Streptococcus zooepidemicus*, an infrequent human pathogen, was associated with a milkborne outbreak of infection complicated with glomerulonephritis.[50] Staphylococcal superantigens may also be involved in the induction of nephritis by triggering the production of high levels of cytokines, formation of circulating immune complexes, and glomerular deposition of IgG, IgA, and complement components.[91]

55.5.2 Erythema Nodosum

Erythema nodosum is an immune-mediated dermatologic complication characterized by painful nodular lesions that change from pink to bluish to brown and are commonly found on the legs and arms. *Campylobacter*, *Yersinia*, and *Salmonella* infections have been associated with the occurrence of erythema nodosum.[4,43,45,95,148,161] The lesions may be recurrent with prolonged fecal excretion of pathogens such as *C. jejuni*.[11]

55.5.3 Kawasaki Syndrome

The etiology of Kawasaki syndrome (KS; also known as mucocutaneous lymph node syndrome or Kawasaki disease) is unknown; however, the clinical features and laboratory findings strongly suggest that KS may be induced by infectious organisms.[24] The syndrome is characterized by vasculitis of large- and medium-sized arteries, in particular, the coronary vessels, fever, polymorphous rash, conjunctivitis, pharyngitis, strawberry tongue, red fissured lips, erythema and edema of the palms and soles, and cervical lymphadenopathy. KS usually affects infants and children less than 5 years of age; in the US and Japan, KS is the most common cause of acquired heart disease in young children.[24] Immunologic features of KS include a marked expansion of T cells possessing the Vβ2 and Vβ8 receptors, increased production of cytokines including tumor necrosis factors and interleukins, and complement activation.[1,88] The powerful immune response that occurs with KS leads to destruction of arterial walls.

Toxic shock syndrome caused by *Staphylococcus aureus* toxic shock syndrome toxin-1 (TSST-1) and streptococcal pyrogenic exotoxins, classified as superantigens, shares many clinical and immunologic features with KS. Superantigen-producing *Staphylococcus* and *Streptococcus* strains may be involved in the induction of KS.[6,32,101,192] Leung et al.[101] isolated TSST-1-producing *S. aureus* and streptococci producing pyrogenic exotoxins B and C from 13 of 16 KS patients, but from only 1 of 15 control patients. The strain isolated from the control patient typically was gold colored, whereas the strains isolated from KS patients were white and produced only low levels or no hemolysin.

55.5.4 Crohn's Disease and Ulcerative Colitis

Both Crohn's disease (CD) and ulcerative colitis (UC) are characterized by chronic inflammation of the gastrointestinal tract. Although there are differences in the pathologic and clinical features of CD and UC, they are classified collectively as idiopathic inflammatory bowel disease (IBD). Because CD and UC resemble gastrointestinal infections caused by infectious microorganisms, and clustering of cases of CD among family members[202] and close contacts[5] have been reported, an infectious etiology has long been suspected. Furthermore, there is evidence that enteric infections are associated with exacerbations and relapses of established IBD.[149] Erythema nodosum, eye abnormalities, arthritis, and other symptoms can occur as extraintestinal manifestations of CD.

One pathogen under investigation as a possible cause of CD is *Mycobacterium paratuberculosis.* Because CD and Johne's disease (JD), which occurs in ruminants and other animals including primates, share similar clinical and pathological features and *M. paratuberculosis* is the causative agent of JD, it has been suggested that the disorders share a common etiology. Cows excrete *M. paratuberculosis* in their milk and colostrum,[176] and the organism apparently is more resistant to pasteurization than other mycobacteria;[27] therefore, it is possible that milk and other foods of animal origin are potential vehicles of transmission of *M. paratuberculosis* to humans. Chiodini et al.[28] reported the isolation of a *Mycobacterium* species from intestinal tissue of three patients with CD, and other reports also have described isolation and identification of *M. paratuberculosis* in individuals with the disease.[37,116,187] Liu et al.,[105] using immunocytochemical techniques, found *Listeria* antigens in intestinal and mesenteric lymph node specimens of 75% of CD patients and *E. coli* and *Streptococcus* species antigens in 57% and 44% of CD patients, respectively. However, the authors suggested that *L. monocytogenes* may have occurred as a secondary infection. Evidence suggesting an etiological role of SLT-producing *E. coli* serotype O2:H5 in UC has been reported,[205] but this finding has not been confirmed. A possible role of bacterial superantigens in the pathogenesis of CD and UC has been described.[14,74,84] Although infectious organisms may be involved in the development of CD and UC, the diseases may have a multifactorial etiology involving dietary, hereditary, microbial, and immunological components.

55.5.5 Hemolytic Anemia

Acute hemolytic anemia, presumably immune-mediated in most cases, has been reported to occur as a complication of bacterial infections due to *Campylobacter* and *Yersinia.*[34,203] Seitz et al.[157] characterized the types of hemolytic anemias in 96 cases in which the hemolytic disease was preceded by a microbial infection. In most cases full recovery occurred within 3 months; however, in 13 patients, the hemolytic disease showed a chronic course. "Warm" or "cold" autoantibodies (antibodies that react best at 37° C or 4° C, respectively) were detected in 17 (17.7%) patients, while in 57.3% of cases the infection-associated hemolytic disease was characterized by alterations of the red blood cell surface due to binding of microbial antigens and in some cases also of complement components.

55.5.6 Miscellaneous

An association between infection with *Yersinia enterocolitica* serotypes and Grave's disease and other thyroid disorders has been suggested.[9,16,210] Patients with various thyroid disorders may possess autoantibodies against thyroid antigens such as thyrotropin (TSH). *Y. enterocolitica* was found to possess a binding site functionally similar to the TSH receptor found in thyroid tissue.[210] Thus, individuals exposed to *Y. enterocolitica* may generate antibodies that cross react with TSH receptors. The antibodies may bind to thyroid tissue, resulting in thyroid hyperactivity. Reports of involvement of specific serotypes of *Y. enterocolitica* are conflicting, and antibodies against *Y. enterocolitica* have been demonstrated in patients with thyroid diseases but also are found in a percentage of healthy individuals.[9] Toivanen and Toivanen[194] concluded that *Y. enterocolitica* does not appear to be a major inducer of thyroid autoimmunity; therefore, further research is needed to determine a role, if any, of *Yersinia* in triggering thyroid disorders.

In adults, the convalescent phase of foodborne illness caused by *Clostridium botulinum* can last for as long as 1 to 2 years. Residual symptoms of botulism include chronic weakness, fatigue, and exertional dyspnea.[177] *Salmonella* infections have caused complications such as orchitis, urinary tract infection, and septicemia.[18,98] Infections caused by antimicrobial-resistant nontyphoidal *Salmonella* strains have increased in recent years, thus rendering difficult the treatment of individuals with complications.[72,98]

56.1 INTRODUCTION

Foodborne disease, defined by the World Health Organization (WHO) as "a disease of an infectious or toxic nature caused by, or thought to be caused by, the consumption of food or water," is recognized as a major international cause of morbidity and economic loss.[105] The WHO estimates that hundreds of millions of individuals worldwide experience diarrheal disease each year, and that many of these cases are foodborne in origin.[106] Most recorded foodborne diseases are microbial in origin and have increased even in industrialized countries. Concern about foodborne diseases is not new, and the fact that they are a worldwide problem of major public health importance and economic loss has been recognized for more than 25 years.[42,82,100,103]

In recent years the economic losses associated with foodborne diseases have attracted increasing attention in North America and Europe; however, it is suspected that the impact of these diseases may be greater in developing countries because of the large numbers of people who are thought to be affected, although few data are currently available to support this. The costs of illness are associated with the investigation, treatment, and prevention of illness, and with loss of productive output, and may affect the whole chain of food production. Thus, the costs of foodborne disease fall both on the public and private sectors and may be extensive both in terms of categories and levels of costs incurred. When outbreaks occur, opportunity costs include public sector resources that are diverted from routine activities often associated with regulation and prevention into the investigation of the cause and the control of disease. In the private sector, financial burdens may be imposed on ill persons and their families as well as on the food industry in general and on the particular company whose product is associated with illness. This chapter examines the rationale behind the economic evaluation of foodborne diseases, discusses the types of cost and their validity, and describes their social and economic implications in terms of estimated national costs of foodborne disease and in the assessment of preventive activities.

56.2 FACTORS AFFECTING INTEREST IN ECONOMIC EVALUATION OF FOODBORNE DISEASE

Economic appraisal of foodborne disease is important in bringing to public attention an essentially preventable illness and in identifying those areas, particularly in the public sector, that are the most costly. However, the most valuable contribution concerns the evaluation of procedures designed to limit or prevent the spread of infection.

Three factors in particular have influenced economists and others to direct their attention to the financial and social impact of foodborne disease. First, it is recognized that foodborne diseases cause significant morbidity and mortality annually, even in developed countries where food safety is well regulated and production and processing standards are protected in law or through codes of practice. [4,22,37,38,41]

Second, there is recognition that the costs to the public and private sectors associated with foodborne illness in general are significant. Although the methods of approach used and types of cost included in published studies vary, the estimated annual costs of salmonellosis and other foodborne disease in the United States (US), Canada, and the United Kingdom (UK) may be in the region of billions of dollars or pounds.[7,39,68,69,79,92,93] The cost estimates given generally have been conservative, but nevertheless indicate that the potential economic impact of these infections at the level of national economy is high. Furthermore, studies that have investigated the impact of human disease-causing organism contamination on the agricultural and food processing industries in the 1970s in Germany and Canada, and more recently in the US, indicate these costs also are high.[23,24,44]

A third, more general factor is growing government concern about the escalating costs of public sector services. The health sector, particularly in industrialized countries, is seen as a major consumer of resources and, therefore, as a legitimate target for both cutbacks and efficiencies.[17,29,31,63,99]

56.2.1 Cost-Benefit Analysis

CBA addresses the question of how to maximize benefits from the resources available and has been used to evaluate the benefits that would derive from the introduction of specific preventive strategies. For example, a CBA of the potential cost reduction associated with human salmonellosis in Scotland that would result from the introduction of universal pasteurization of milk was instrumental in bringing about such legislation.[19] Subsequent studies confirmed the effectiveness of this approach in virtually eliminating milkborne *Salmonella* infection and reducing *Campylobacter* infection.[74] Studies of poultry irradiation in Scotland and England and Wales used a similar methodology to estimate the long-term benefits that would accrue largely from saved health care costs and prevention of lost production due to sickness absence.[79,107] A more recent study of the benefits of HACCP regulations for meat and poultry plants in the US suggested a net benefit if the costs associated with *Campylobacter jejuni/coli*, *Clostridium perfringens*, *Escherichia coli* O157:H7, *Listeria monocytogenes*, nontyphoid *Salmonella* infection, and *Staphylococcus aureus* were reduced by only 20%.[23]

56.2.2 Cost-Effectiveness Analysis

CEA assumes a single outcome, and the evaluation is concerned with meeting this outcome at the least cost. Unlike CBA, CEA can use physical and monetary measures of outcome, but is limited in that difficulties arise when trying to measure more than one outcome. To obviate this, CUA converts outcome measures to a single index such as the quality-adjusted life year (QALY).[99]

56.2.3 Cost-Utility Analysis

The QALY was proposed as a method for estimating the outcomes of health interventions and has been used extensively in CUAs.[108] QALY is a measure of the difference in well-being between a state of perfect health and a state of impaired health. The value of avoiding a debilitating health condition therefore is calculated as the measure of QALYs gained (by prevention or cure) multiplied by the expected remaining years of life. Mauskopf and French[49] have suggested the use of QALYs as a generalized approach for comparing the value of avoiding illness using published data to estimate the value of avoiding morbidity and mortality.

56.2.4 Cost of Illness Approach

The COI approach is more limited in its objectives and usually is concerned with delineating the types and quantifying levels of costs involved, and expresses benefits as costs avoided.[21] The COI approach, frequently adopted in the economic evaluation of foodborne disease, aims to determine the cost of illness to society, usually within a specified time period, although costs avoided may not reflect the real cost of avoiding illness and exclude intangible costs related to pain and suffering. Typically, this approach tends to concentrate on the direct medical and nonmedical costs of illness and indirect costs resulting from lost productivity due to sickness absence, or premature death.

It is difficult to assess the value to society of the activities of the young, the elderly, the unemployed, homemakers, and the disabled. Nonetheless, the value of these activities should be included, and various strategies have been explored to quantify them. These costs can be a significant factor in calculations, although it has been suggested that, overall, the COI approach gives a low estimate of the true costs.[40] Some authors have proposed an approach that combines COI estimates with those for intangible costs estimated using, for example, the willingness-to-pay (WP) approach.[79] While this gives higher overall estimates of the costs of illness, greater care is needed to avoid double counting and inclusion of inappropriate cost categories.

56.2.5 Valuing Health

There is not necessarily a correspondence between the cost of an illness and the value a person would place on not having the illness (ie, avoiding the pain and suffering). A modified WP approach of Landefeld and Seskin[45] provides an alternative method of appraisal of the value an individual puts on avoiding foodborne disease.[70] The WP approach seeks to measure the individual's valuation of health status in terms of what he or she would be willing to pay, or forgo, to avoid risk of death, disability, or illness. This methodology is compatible with economic demand theory in that it reflects the assessment of the individual's health and health needs and will be modified by the ability to pay.[28] Surveys, for example, have attempted to assess consumer willingness to pay extra for safer food; a survey in the UK found that some consumers would pay more for safer food.[3]

Difficulties also arise in relating cost to the severity of illness, which may vary from very mild to death. Some studies have ascribed cases to various categories depending on the level of treatment required; however, even within these categories, there will be a range of severity. The treatment received may be partly a function of actual severity and partly a function of the individual's perception of need; this particularly may be so in individuals who do not require hospitalization. In some studies, the average cost per case may not adequately have reflected the relatively mild illness that probably is experienced by most infected persons. In one publication, however, an allowance was made for mild illness in most people in estimating cost attributed to unreported cases of foodborne illness; in another study, cases were ascribed to one of four severity classes related to death or the level of medical treatment required.[64,65,67]

In the cost benefit study of milk pasteurization in Scotland, estimates were based on UK Ministry of Transport data for assessing injury.[18] The same approach was adopted in the cost analysis of a *Salmonella* outbreak;[64] however, there are difficulties with this approach. How well, for example, do the levels of severity of salmonellosis compare with an accident injury? Little information about the severity of outbreaks of salmonellosis is available. Some information can be derived from the type of medical service sought by individuals, thus "death," "hospitalization," "treatment by a GP," and "no medical attention sought" have been used.[22,64]

In an alternative approach, subjective assessments by patients of illness severity were used to create a severity index that correlated strongly with more objective measures, such as length of illness and use of medical facilities, and with illness-related costs.[79] When applied to national estimates of *Salmonella* costs, this approach yielded, overall, lower average costs than those based on the level of use of medical services and outcome (Table 56–1). This result was attributable mainly to the ability of the severity index to reflect a lower COI of less severe illness, particularly where these related to family costs and loss of production. Public health investigation and treatment costs were the same.

56.3 APPROACHES TO ECONOMIC EVALUATION IN PUBLIC HEALTH

The modern public health function, founded on concern for sanitary hygiene and the control of epidemic disease, and currently defined as "the science and art of preventing disease, prolonging life and promoting health through organized efforts of society," usually has been assumed to be a government responsibility in terms of the enactment of public health laws or regulations, with enforcement at the local level.[2] Expenditure on public health has been regarded as an investment in human capital that benefited the national economy. In an early example, Calkins, commenting on sanitary legislation in England from 1875 to 1890, noted that the death rate in England declined between 1880 and 1889 and that the value of lives saved, based on William Farr's estimated value of life, was $650 million compared with $583.5 million spent on sanitary improvements.[15,30] Calkins concluded: "Thus in ten years the country has more than regained the sum that was spent for sanitary improvements in the fifteen years; and in this calculation nothing figures for maladies avoided . . . spared grief, better health and happier lives." In terms of foodborne disease, economic theory provides a framework for evaluating and comparing the cost implications of, for example, human illness or implementation of a risk-reducing activity, with the benefits of a risk-reduction activity such as milk pasteurization or application of the Hazard Analysis Critical Control Point approach (HACCP) to a production process. The tools of economic evaluation include cost-benefit analysis (CBA), cost-effectiveness analysis (CEA), cost-utility analysis (CUA), and cost-of-illness (COI) studies. These were developed to assist decision making, particularly in the public sector where normal market forces cannot operate.

56.4 CATEGORIES OF COSTS ASSOCIATED WITH FOODBORNE DISEASE

The costs associated with foodborne disease fall under the main headings of public sector costs, costs to ill individuals and their families, costs to the national economy, food industry-related costs, and costs of legal action. Some of the specific costs evaluated in published studies are listed under these categories in Exhibit 56–1.[24,25,68,70,79,95] These may be subdivided into tangible costs, which have a directly measured monetary value, and intangible costs, which do not.

The tangible costs may be presented as direct costs to the affected person or the implicated food producer and include costs associated with providing health care or to an intervention activity. Additionally, tangible indirect costs relate to resource expenditure resulting from participating in an intervention activity or the results of illness, such as income loss because of time off work. Indirect costs to the

Exhibit 56–1 Types of Costs Potentially Associated with Foodborne Illness

Public Sector Costs:
Investigation costs for epidemiology and laboratory analysis
Costs for controlling outbreak including publicity, assisting product recall and premises cleanup, travel
Additional surveillance costs
Treatment

Costs to Ill Individuals or Their Families:
Physician visits
Medication, operations
Hospitalization
Vocational and physical rehabilitation, including home modification
Convalescence
Pain and suffering
Income or productivity loss
Leisure time loss
Home care of ill person
Cancelled arrangements
Purchase of comfort
Education time lost
Risk aversion costs
Averting behavior costs
Travel costs
Value of lives lost (willingness-to-pay portion)

Economy:
Production loss to national economy
Government intervention
Value of lives lost (human capital portion)

Food Industry Costs:
Product recall
Reduced demand for products
Destruction or reprocessing of products
Purchase of new equipment
Design change at plant
Educational programs for staff
Hiring of new/extra staff to deal with crisis
Increased testing of ingredients and final product
Advertising costs to recover market position
Increases of loans
Increased insurance premiums
Possible redundancy with lay-offs or closure
Adverse effect on related business

Legal Action:
Fines, seizures
Jail sentences
Legal suits and out-of-court settlements
Legal costs for lawyers

Source: Data from references 24, 25, 68, 70, 79, 95.

food producer can have a significant effect on business and include loss of public confidence in a particular food that may affect product sales across the food sector, depressing demand and resulting in cutbacks in production. Because some costs could be included in more than one category, particular care is necessary to avoid double counting.

Intangible costs are not directly measurable in financial terms, but they are important to the description of the impact of illness. There is discussion about the methodology of valuing such costs; however, the need to take them into account is agreed on by economists.[54] The intangible costs of illness include pain and suffering and death. Death represents both a loss to the affected person and to the families involved with possible financial implications and a cost to the economy in terms of the loss of the future production potential of the individual. Attempts to place value on pain and suffering have used legal settlements and the WP approach. For example, the UK Department of Transport has used WP studies to create a scale of values for injuries of different severity or disability and death.[27]

56.4.1 Public Sector Costs

Public sector costs include the resources expended on the investigation of cases, the investigation and control of outbreaks, and medical treatment. These activities could impose costs on local public or environmental health authorities; public health physicians; and laboratories and government departments associated with health, agricultural, and environmental issues; provision of medical services, including family practices and hospitals, where these are funded through a government-administered health service. The treatment costs themselves may be defrayed by national insurance schemes across society, as in the UK, or may be borne directly by the individual or the private sector through personal health insurance schemes.

56.4.2 Costs to the Individual and Family

It is important to distinguish public sector treatment costs from those medically associated costs incurred by ill individuals and their families. Direct costs to individuals and their families may include the costs of seeking treatment (eg, costs of travel to doctor, hospital), medicines, costs of care, and the costs of making oneself "comfortable" (eg, purchase of leisure materials and dietary supplements). Indirect costs include disability, loss of income resulting from missed work opportunities or having to change vocation and accept a lower wage, and retraining. Individuals and families may incur considerable loss from cancelled arrangements including holidays and education fees, and may spend large amounts to purchase comfort. This may include replacement of bedding, cleaning and disinfecting materials, dietary supplements, and entertainments. The types of losses and costs incurred by individuals in a study of 1,482 individuals with salmonellosis in the UK in 1988 are shown in Exhibit 56–2.[79]

Changes in lifestyle, particularly eating habits, may result in some foods or restaurants being avoided and more expensive, and perceived "safer" alternatives to the foods implicated in outbreaks may be purchased. Little detailed information on the profile of these costs exists in the context of foodborne illness.

56.4.3 Leisure Time and Activities

Loss of leisure time has been evaluated at the same rate as loss of productive output, allowing different amounts of leisure time for weekdays and weekends, and including a gender and age differential and assumptions about employment status in the calculation of average hourly wage rates.[24,44] This approach assumed that leisure time was valued at least as much as time spent at work.

56.4.4 Value of Life

Estimates of the costs of deaths associated with foodborne disease are difficult to make. Because many of the reported deaths occur in people with underlying medical conditions and the elderly, account needs to be taken of the contribution that the foodborne disease actually made to death. Differentiation should therefore be made between those instances where foodborne disease caused death in a healthy individual, for example, in a community outbreak of botulism or veritoxin-producing *Eschericheria coli* (VTEC) infection, and those situations where infection or intoxication contributed to death, for example, in an outbreak in a home for the aged or on a hospital ward for chronically ill patients. Lastly, foodborne infection or intoxication may be incidental to the final outcome when infection occurs in a terminally ill person and advances the time of death. It therefore becomes necessary to explore these possibilities if a reasonable estimation is to be made of the value of lives lost. Basing the value of lives lost simply on application of a monetary figure to deaths where foodborne infection was recorded would overestimate costs, although this is the approach most commonly adopted simply because of lack of detailed information about outcome and underlying factors. In an analysis of *Salmonella*-related deaths in the UK, there was a significant difference in overall costs of death depending on whether or not cases were differentiated on the contribution of the *Salmonella* infection to outcome.[79]

Two approaches to valuing life have been adopted by most researchers examining the costs of foodborne illness: the human capital (HC) approach, which approximates the effect of permanent or temporary disability or death to the discounted loss of productivity (usually equated to total costs of employment) of the affected individual, and the WP approach (see Section 56.2.5). Both approaches were recommended as appropriate to COI studies.[21] There are, however, drawbacks to these approaches. First, on grounds of social bias, that the HC approach to valuing life on the future production potential of individuals is influenced by age, gender, and race, and therefore values individuals according to these criteria. The WP approach has drawbacks relating to the validity and consistency of the values derived. A combined approach proposed by Landefeld and Seskin gave a midrange estimate of the value of life between that derived by the HC and WP methodologies.[45] Current debate centers around the methodology of valuing life rather than whether or not it is possible.

The value of life, which clearly should be included in cost benefits of preventive measures, will be strongly influenced by the estimated number of lives lost. For example, in cost-benefit studies of milk pasteurization and poultry irradiation in Scotland and of preventing *Salmonella napoli* infection following an outbreak in England in 1982, the results were significantly influenced by the assumptions made about the numbers of deaths and the adopted

Exhibit 56–2 Types of Costs Incurred by Families in a Study of 1,482 Cases of Salmonellosis in the UK in the Period 1988–1989[79]

ADDITIONAL EXPENDITURE	
Seeking treatment:	Travel to and from family doctor and hospital Refreshments Prescribed medicines Nonprescribed remedies
Comfort:	Clothes and toiletries for use in hospital Leisure items (books, games, videos) Dietary supplements (food and drink) Communications (telephone calls) Replacement clothing and bedding Travel by visitors and caregivers Additional home heating
Hygiene:	Cleaning materials Disinfectants and bleach
UNEXPECTED LOSSES	
Holidays:	Time lost by ill person and accompanying friends and family Curtailed or extended stay Insurance excess Excursions not taken
Other:	Cancelled or postponed arrangements such as theater trips, weddings, family parties Prepaid child-care and education fees not used Unused travel season tickets or vouchers

method of valuing life.[19,65,107] This is also clearly seen in the significant contribution that high estimates of deaths made to the overall costs of foodborne disease in the US.[67,68]

56.4.5 National Economy

Lost production has proven to be a significant cost to the economy. These costs may be generated by absence of the affected person from work due to illness or premature death and by family or friends taking time off to take care of those who are ill.[65] The lost productive output was estimated to be up to half of all the tangible costs of two of three outbreaks and a study of national *Salmonella* costs in the UK between 1981 and 1988, although the proportion varies by outbreak (Table 56–2).[18,56,80,107] In these studies, production loss was calculated on production potential of the individual being equivalent to at least the gross daily employment costs of that individual.[55] This is likely to be an underestimate because it does not account for the profit of a firm that results from the employees' activities. Aggregated employment costs were subject to the proportion of working adults involved in an outbreak, and were correspondingly lower in a *Salmonella* outbreak in 1982 when more than 60% of cases were in children. Further debate may be necessary to allow for differences in wage rates that relate to age, gender, and status within a company. For example, labor market data may undervalue a woman's contribution to the labor force. The removal of this gender bias significantly increased productivity losses.[64]

There is debate about the extent to which absence from work affects productivity, and it could be argued that the work will be made up either by slack in the system or by imposing extra work on other members of staff. It also could be argued that there is

Table 56–2 Lost Production as a Proportion of Total Costs in Three Salmonella Outbreaks and a National Study of Salmonellosis Costs in the UK

Type of Study	*Year*	*Total Cost (£)*	*Production Lost (£)*
Salmonella outbreak	1981	84,089	36,864 (44%)*
Salmonella outbreak	1982	504,808	15,356 (3%)*†
Salmonella outbreak	1984	8,364	3,270 (39%)*

† 60% of cases were in children aged under 15 years.

Source: Data from references 18, 56, 64, 80.

no productivity loss if there is unemployment in the system on the assumption that replacement staff can be taken from the pool of unemployed. For foodborne disease, the presence or absence of unemployment is largely irrelevant as absence, in most cases, will be short and the costs of a company seeking alternative employees prohibitive.

56.4.6 Losses within the Food Industry

Losses may be incurred by the food industry when a product is implicated as a source of illness or when contaminated products are withdrawn from sale. Costs borne by the food industry at the primary producer (farm), manufacture, import/export, processing, or service and retail stages include direct and indirect costs. Immediate loss of business may occur when a food service outlet or manufacturer is identified as a source of infection. The cost to the company may be substantial; consumers may switch to an alternative brand or product, resulting in severe financial effects on the firm. For example, after a manufacturer's withdrawal of infant feed products in the UK in December 1985 following an outbreak of *S. ealing* infection, parents switched to other brands and there was a significant loss in the sale value of the company.[73] The effect on the wider economy may be minimal, however, unless long-term unemployment results from, for example, loss of public confidence in a product or plant closure.

Where a specific product is implicated as a cause of illness, it is liable to be recalled, held for the period of investigation, and eventually destroyed. Recall may be expensive and involve national and local government agencies as well as the food industry, and product destruction must be counted as an outright loss.[77] Recall costs in seven outbreaks were US $83,000 to $9.8 million and were 24% to 99% of the total outbreaks costs (Table 56–3).[89] Withdrawal of a product or closure of a restaurant may result in a decline in public confidence, which may then take years to recover and may affect sales of similar products of different brands. For example, decline in public confidence had a major impact on the manufacturer in the *S. ealing* outbreak mentioned above. By 1989 (4 years after the outbreak), the company had recovered only half of its former market share; one production unit was closed and about 200 jobs had been lost.[85] Similarly, sales of corned beef in the UK were depressed for many years following a typhoid outbreak associated with canned corned beef in 1964, and sales of canned salmon in the UK were affected for several years after cases of botulism were associated with canned products from North America in 1974.[89] Even for food service establishments that have been implicated in outbreaks, the costs may be high. In a study of 17 outbreaks, mainly in North America, the median cost per case was $788 in 1983 dollars.[88]

Other direct costs may result from fines and the need for renovation and cleaning of premises, replacement of defective equipment and training of present or new staff, and promotional costs. It could be argued that at least some of these costs, including items of capital expenditure on new equipment, may have occurred anyway and that the outbreak only hastened the expenditure. However, because it is unlikely to be known when this expenditure would take place and the producer would want to restart production as quickly as possible, they arguably could be included in the direct cost of the outbreak.

Staffing costs may include salaries of staff suspended because they are excreting a pathogenic organism, or salaries of staff laid off while the premises

Table 56–3 Food Industry Losses in 9 Selected Outbreaks of Foodborne Illness or Recalls in Various Countries

Agent	*Product*	*Number of Cases*	*Loss of Product ($)**	*Recall Costs ($)**	*Production Stoppage ($)**	*Total ($)**

(IAMFES).

are closed or being renovated and cleaned. Alternatively, costs could arise from overtime or temporary employment of additional staff to cover for those suspended or to help in cleaning.

56.4.7 Government Financial Commitment to Public Food Safety, and the Industry Sectors

Further costs to the economy can occur when governments act to intervene by increasing surveillance or research in the area of foodborne disease or to support a sector of the food industry affected by a lack of product confidence. For example, the UK government, in 1989, instituted a series of inquiries in response to public concern over *Salmonella*-contaminated eggs. These, and concerns over listeriosis, led to formation of an Advisory Committee on the Microbiological Safety of Food (ACMSF), and a number of working groups were convened to examine all aspects of food production and to commission research into product safety and disease surveillance.[1,2] In addition, the UK government pledged £7 million to support, through compensation, sectors of the egg industry affected by the government policy of slaughtering infected layer flocks.[51] More recently, the UK government has acted to support the UK beef industry with compensation following policies to "protect" the public from the consequences of bovine spongiform encephalopathy (BSE).[53] Other examples included payment of US $5 million (1983 prices) by the Canadian and Alaskan state governments in promotional costs to support the salmon industry following public loss of product confidence after a botulism incident in Belgium in 1982, and payment of about US $3.6 million by the Canadian government to support a chocolate producer following association between their products and *Salmonella* infection in 1974, thereby offsetting costs of unemployment.[89]

Indirect industry-related costs may include a loss in the actual value of the company; for example, through a decline in share values. The company in the *S. ealing* outbreak had been on offer for sale at £40 million but following the outbreak eventually was sold for £18 million, a £22 million loss in its value.[73,78] Industry losses in the US in the 1980s resulting from *Listeria* contamination in commercial foods were estimated to be more than US $9.3 million or about 0.1% to 0.2% of the value of sales.[72] Between 1986 and 1988, to reduce contamination with *Listeria* spp., food processing plants changed production lines, increased laboratory testing, performed major cleanups and increased sanitation, replaced equipment, and educated workers and management.

56.4.8 Legal Costs

Legal damages may result from government regulatory actions and legal suits initiated by individuals or by companies who feel that a warranty or contract has been broken. The costs involved are difficult to obtain, but sometimes are mentioned in newspaper articles. Some of these legal costs can be huge and may account for a major proportion of total costs to a company of an outbreak where they have been included.

Products that appear to be in violation of an act or regulation may be seized and the companies producing or selling them may be fined; licenses may be withdrawn and officials jailed. For instance, in Wisconsin in 1965 and Quebec in 1977, cheese worth US $124,400 and US $320,000, respectively, was seized and destroyed because of the presence of *S. aureus* enterotoxin.[89] Company fines have ranged from $500 to $12,000 in the US, and owners of violative companies may be jailed or put on probation as well as fined as occurred with the 1985 *Listeria monocytogenes* outbreak due to a Mexican-style cheese in California and an *E. coli* O111 outbreak associated with mettwurst in New South Wales, Australia. In the UK, meat producers failing to comply with meat hygiene or meat processing regulations designed to limit the threat of BSE transmission to humans face severe financial penalties.

Litigation is sought when an individual claims to have a just cause, irrespective of violation of regulations or codes of practice. Those claims most frequently documented are associated with large outbreaks that receive wide publicity. Settlements can be awarded in court decisions, out-of-court settlements, or through worker compensation boards. Reasons given for taking legal action include illness and loss of job when individuals are identified as carriers in hospital or food retail situations. Ten settlements in the US and Canada following outbreaks ranged from $12,306 to $1.9 million (1985 US and Canadian dollar values) and from 1.2% to 95.3% of the total incident costs (Table 56–4).[90] Settlements were much higher for two *S. aureus* outbreaks (Can $1.5 million to $1.7 million) and two botulism outbreaks (US $0.6 million to $2.0 million); these ranged from 22% to 84% of total incident costs.

Following a multistate outbreak of *E. coli* O157:H7 infection in the US in 1993 (not included in the table), millions of dollars have been paid for medical and hospitalization costs and to franchisees who lost money due to bad publicity. A few individual settlements were publicized, such as a high figure of US $15.6 million being given to one chronically ill child.[9] The final total will be in excess of US $100 million (C. Bartleson, personal communication). The payment made by a major UK airline following a *Salmonella* outbreak in 1984, which resulted in more than 600 illnesses in passengers and two associated deaths, was in the order of several million pounds sterling (British Airways press office, personal communication).[12] In 1991 a farmer in England was ordered to pay £33,000 damages to the families of two customers who died from *Streptococcus zooepidemicus* infections after drinking contaminated raw milk.[86] Settlements thus vary considerably in amount, but generally, the more severe the illness, the larger the settlement. Furthermore, it is probable that in most instances only those willing to take legal action will normally get any kind of settlement, although the use of class action suits may increase the number of persons receiving compensation.

Companies also will sue other companies where contaminated ingredients have resulted in illness or product loss. For instance, in 1978 a club sued a bean canner for allegedly supplying beans that contained *Clostridium botulinum* toxin that caused 34 cases of botulism. The club, which had been sued by the victims, won US $1.5 million from the canner in 1981.[48,89] Typically, insurance companies pay most of court and out-of-court settlements; however, this potentially results in increased insurance premiums not only for the producer or retailer involved, but also for the industry if sufficient claims are made. The effect of legal action may not be represented adequately by the eventual awards; the process may take several years to complete and cause considerable stress to all concerned.

56.5 ESTIMATED CASES AND DEATHS DUE TO FOODBORNE DISEASE

Case estimates are important for economic assessment because numbers of cases and deaths affect the total cost of foodborne disease. These estimates often are calculated as a multiple of an average cost per case. Many industrialized countries report cases and outbreaks of foodborne disease, but the type and extent of reporting varies considerably. On a population basis, cases may range from 7 to 123 per 100,000 population, and the ratio of cases to outbreaks shows a similar amplitude indicating that, in some countries, only moderately large or large outbreaks are included in the final figures, although smaller outbreaks may have been investigated. In contrast, relatively few countries have attempted to estimate the number of cases and so determine the associated annual economic burden. US figures, based on extrapolation of sentinel county studies, health surveys, and

Table 56–4 Liability Costs in 10 Court and Out-of-Court Actions Following Foodborne Disease Outbreaks in North America

expert opinion put estimated case numbers (1.4 to 33 million annually) much higher than the recorded numbers from the passive reporting system (about 18,000 annually); and the number of people estimated to have died from foodborne disease to be between 500 to 9,000 annually.[22] Estimates of foodborne disease in Canada, including diseases associated with seafood toxins, suggested about 2.2 million cases each year.[92,93] Both sets of data have been determined by accumulating estimates for specific foodborne diseases. For a more detailed discussion of case estimates, see Chapter 37.

Bennett et al., in estimating the number of people who died in an outbreak of foodborne illness in the US, assumed that the proportion of cases to deaths was the same for both known case numbers and extrapolated numbers with a total number of deaths close to 9,000.[11] Other researchers consider that there are no deaths in the extrapolated case numbers or that the proportion of deaths is much reduced; this would therefore result in lower estimates of the cost of illness.[22,79,96,101] Recently, the widely quoted 9,000 death figure for the US has been criticized as being too high.[102]

56.6 NATIONAL ECONOMIC STUDIES OF FOODBORNE DISEASE

A relatively small number of studies of the national costs of foodborne illness in general or specific foodborne illnesses are reported in the literature, largely from North America and Europe; however, five estimates of national costs related to disease problems in Asia and Latin America also are noted in this section. The costs derived in these studies were dependent on estimates of the annual numbers of cases and on cost-per-case data derived from studies of outbreaks. Most have concentrated on estimating costs associated with medical treatment and productivity losses; many categories of costs were excluded, and the amounts derived, therefore, represented the minimum costs of disease. Exceptions to this were a national study of *Salmonella* infections in England and Wales in 1988–1989 that was based on a detailed survey of individual cases, and national studies of *Salmonella* costs in Germany and Canada that sought to quantify a wide range of cost categories.[24,44,80] These are reviewed in detail in the next section.

The range in categories of costs included in various studies, differences in the range and types of agents included, methodologies used in extrapolating to national totals, and differences in population sizes and economic activity make it difficult to compare costs from one country with another. Limitations on the cost categories included and a conservative approach to estimated numbers of cases indicate that the apparently large costs reported may underestimate the true impact of these diseases. Some of the more widely reported national studies of foodborne disease in general or of specific agents are reviewed below.

56.6.1 Canada

The cost of an estimated 2.2 million cases of bacterial foodborne disease per year from 1978 to 1982 in Canada was Can $1.175 billion, of which salmonellosis, *S. aureus* intoxication, and *E. coli* O157:H7 infections were the most expensive (Table 56–5).[93] The estimated 627,200 *Salmonella* cases cost Can $846 million at a cost per case of Can $1,350. This compared with a subsequent estimate of 847,400 cases costing Can $203.2 million at a lower cost per case of $240.[25]

Botulism in native peoples from improperly fermented fish or marine mammal products was estimated at Can $2 million annually ($7,200 per case and $100,000 per death). These relatively high costs reflected the costs of evacuation of patients from remote communities, hospitalization, and illness investigations in six incidents between 1984 and 1986.[91] Outbreaks arising from commercially produced food contaminated with *Clostridium botulinum* were expensive, costing from Can $1.5 to $160 million;[89] therefore, it is not surprising that the cost of botulism in Canada was estimated at Can $17 million annually with the highest cost-per-case figure, Can $340,000, of any agent. Other agents included an estimated 8,400 foodborne cases of giardiasis, trichinosis, and taeniasis that were estimated to cost Can $34.8 million or $4,140 per case; most illness was associated with the first two parasitic diseases.[93]

In addition to microbial food poisoning, assessments of the number of cases and costs related to an estimated 3,150 plant poisonings (Can $1.0 million), 29,400 chemical poisonings (Can $8.4 million), and 4,370 illnesses associated with consuming animal products—mainly seafood toxins—costing Can $10.3 million have been made.[93]

The estimates of illnesses associated with seafood toxins recently have been revised to indicate fewer cases and a lower overall cost of Can $820,000.[98] A further Can $4.7 million were related to fish and shellfish monitoring and analysis to prevent illness

Table 56–5 Estimated Annual Numbers of Cases and Deaths and Costs of Foodborne Disease in Canada

Etiological Agent	*Reported Foodborne Cases**	*Estimated Cases†*	*Estimated Deaths*	*Estimated Costs ($ million)***	*Average Cost per Case ($)***

from commercial products. One amnesic shellfish poisoning episode with at least 107 cases and 3 deaths caused by consumption of domoic acid in mussels in 1987 was estimated to have cost Can $8.4 million for illnesses, deaths, and lost business through adverse publicity. Such was the devastating impact of this intoxication on the lives of those affected and the local economy that monitoring of shellfish was enhanced to prevent further illness.[16,97]

56.6.2 United States

A comparison of two sources of estimated annual cases and costs of foodborne disease in the US has been made (Table 56–6).[95] The 6.3 million cases and 7,041 deaths at an estimated cost of US $5.8 billion estimated by Roberts[68] were significantly lower than the 12.6 million cases and 523 deaths costing US $10.7 billion proposed by Todd.[94] The difference reflected the inclusion of 7 million cases from seafood toxins, bacterial, viral, parasitic, chemical, plant, and unknown agents not considered by Roberts and marked variations in estimates for number of cases and deaths from specific pathogens; Roberts used COI estimates including medical and productivity costs, whereas Todd added some industry and legal costs.

Revised estimates published in 1996 for a limited group of bacterial pathogens proposed totals of 3.6 to 7.1 million cases and 1,600 to 6,500 deaths, with associated costs of US $2.9 to $6.7 billion for six diseases (Table 56–7).[13] The estimates were based on medical costs and costs of lost productivity; however, there were differences in how they were evaluated. Medical and loss of productivity costs for *Staphylococcus aureus* and *Clostridium perfringens* were calculated on the basis of annual cases multiplied by average annual costs for a previous study

Table 56–6 A Comparison of Preliminary Annual Case and Cost Estimates for Specific Foodborne Diseases in the US

Etiology	*Estimated Costs*		*Estimated Deaths*		*Estimated Costs ($ million)**

Roberts, Human Illness Costs of Foodborne Bacteria, *American Journal of Agricultural Economics*, Vol. 71, pp. 468–474, © 1989, American Agricultural Economics Association, and E.C.D. Todd, Preliminary Estimates of Costs of Foodborne Disease in Canada and Costs to Reduce Salmonellosis, *Journal of Food Protection*, Vol. 52, pp. 586–594, © 1989, International Association of Milk, Food and Environmental Sanitarians, Inc. (IAMFES).

updated to 1993 prices.[68] For *Salmonella, Campylobacter, E. coli* O157:H7, and *Listeria*, cases were divided into one of four severity groups to which costs were then applied before aggregation. For the latter two diseases, some chronic implications also were included in the estimates. In addition, recent estimates of *Campylobacter*-associated Guillain-Barré syndrome in the US were between $0.26 and $1.86 billion annually. Combining this total with estimated costs of foodborne campylobacteriosis indicated an annual cost of $0.8 to $10.1 billion.[13,14] These results suggest the sequelae of foodborne infections may have a significant, and as yet undetermined, impact on the overall cost of foodborne disease.

The number of annual foodborne cases and deaths presented in Table 56–7 was based on current best estimates, and the authors point out that the estimates will be subject to revision as improved data become available. For each pathogen, only the proportion of all cases that were foodborne are shown in Table 56–7; this proportion varies from 17% for *Staphylococcus aureus* infections to 100% for *Clostridium perfringens*. The authors acknowledge that the estimates given undervalue the real economic cost of foodborne illness to society. First, a number of significant human pathogens are excluded from the COI analysis, and second, intangible costs such as pain and suffering and lost leisure time of the affected people and their family, food industry related costs and government resources used to investigate, and control incidents were not included. However, the template presented provides a consistent approach for estimating national costs.

Table 56–7 Annual Estimated Cases and Costs for Selected Foodborne Pathogens in the US

Pathogen	*Foodborne Cases*	*Foodborne Deaths*	*Human Capital Approach ($billions)**	*Labor Market Approach ($billions)**
C. jejuni or *coli*	1,100,000 to 7,000,000	116 to 564	0.8 to 5.7	1.6 to 10.1
C. perfringens	10,000	100	0.1	0.5
E. coli 0157:H7	16,000 to 32,000	63 to 156	0.16 to 0.3	0.3 to 0.7
L. monocytogenes	928 to 1,767	230 to 485	0.1 to 0.3	1.3 to 2.4
Salmonella	696,000 to 3,840,000	870 to 1920	0.9 to 3.6	4.8 to 12.3
S. aureus	1,513,000	454	1.2	3.3
Toxoplasma gondii	*260*	*40*	*3.3*	*7.8*
Total	**3,309,000 to 12,400,000**	**1,900 to 3,700**	**6.6 to 14.5**	**19.6 to 37.1**

* US $ (1996 prices).

Source: Adapted from J.C. Buzby and T. Roberts, Guillain-Barré Syndrome Increases Foodborne Disease Costs, *Food Review*, Vol. 20, pp. 36–42, © 1997, Economic Research Service, U.S. Department of Agriculture.

A way of combining costs of sporadic and outbreak cases and the effect of severity, sequelae, and deaths has been suggested.[95] If it is assumed that there are an estimated 2,000,000 cases of salmonellosis per annum in the US, the cost could be US $1,026 per case for a total of US $2.1 billion (Table 56–8). This approach could be expanded to other diseases.

56.6.3 Croatia

An alternative method was proposed for estimating the national costs associated with about 8,500 cases of foodborne illness, most due to *Salmonella* infection, that occur annually in Croatia.[61] No extrapolation was made to account for nonreported cases. Published foodborne illness costs in Canada, Sweden, the UK, and the US were multiplied by the gross national product (GNP) per capita in Croatia and divided by the GNP per capita in these other countries. Thus, a salmonellosis case costing US $1,350 in Canada or the US would cost only US $280 in Croatia. If this assumption is correct, the estimated cost of the 8,500 cases in Croatia would be about US $2 million. This approach may be applicable for other countries that do not have the resources to determine actual costs, although the GNP may not be the only factor to consider.

56.6.4 Cholera in Peru

The cholera outbreak, caused by *Vibrio cholerae* O1, that has been spreading through South and Central America since 1990, is reported to have had a devastating impact on the economy of Peru, the first country to be affected. Cholera now is endemic in most Central and South American countries with more than 600,000 cases and 5,000 deaths reported from 20 countries. In Peru, there were nearly 500,000 cases in 1991, with foods and beverages from street vendors being major factors in infecting the population.[62]

The economy of Peru was affected by loss of revenue from tourism and food, lost productivity from absence from work, and increased medical costs; in addition, local food industries have suffered depressed demand for their products.[59] Total costs for 1991 were determined to be $495 million, of which the greatest losses were for reduced tourism (US $147 million), local fishery sales (US $32 million), exports (US $28 million) and street food vending (US $16 million), health care for cholera patients (US $33 million), and lost productivity due to illness and deaths (US $26 million). No estimate was made for lost leisure time, cost of self-medication, and drugs purchased. However, there was also a prediction that future deaths would cost the economy US $234 million in lost production. Other Latin American countries probably are experiencing similar but lesser economic effects; the Peruvian situation received high and damaging publicity throughout the world. Cholera is expected to remain endemic in most of Latin America for many years to come.

56.6.5 *Staphylococcus aureus* in India

An outbreak of *S. aureus* intoxication in Hyderabad City, India, affected 64 people for an estimated cost of US $673.[83] This is a low amount compared with industrialized countries, but not for residents of a developing nation. About 1,000 *S. aureus*

Table 56–8 Combined Costs per Annum of Sporadic and Outbreak Cases of Salmonellosis in the US[+]

Type of Case	*Establishment Responsible*	*Severity of Illness*	*Number of Cases*	*Costs/ Case ($)*	*Total Costs ($ million)*	*Cumulative Costs/Case ($)*

cases are recorded each year in the same city.[83] If it is assumed that only 1 in 100 cases are reported (possibly a low estimate for a mild disease), and the cost per case is the same as in the outbreak (US $11.60), the estimated 100,000 *S. aureus* cases in Hyderabad City annually cost about US $1,160,000. Extrapolation to the whole country suggests annual costs for an estimated 34,000,000 cases would be US $340 million.

56.6.6 Opisthorchiasis in Thailand

The liver fluke *Opisthorchis viverrini* is the main cause of foodborne parasitic infections in Thailand that arises from the consumption of raw or undercooked fish. As many as 60% of the work force is estimated to be infected in the northern part of the country. On the assumption that workers are off work for a total of 9 days each year from three separate infections, and that they require hospitalization and drugs, the overall cost of illness is thought to be about US $99.9 million annually.[71]

56.6.7 Neurocysticercosis in Latin America

The estimated annual costs of this disease were reportedly US $85 million in Brazil and $195 million in Mexico, indicating the significant impact of foodborne disease in developing countries as well as in industrialized nations.[71]

56.6.8 Fungi and Aflatoxins in Southeast Asian Countries

Chronic effects of microbial agents are not usually estimated; however, an attempt was made to estimate the effects of aflatoxins in three Southeast Asian countries.[47] The cost of premature death from primary liver cancer and disability and morbidity from liver cancer attributable to aflatoxins in corn and peanuts was estimated to be Australian $228.5 million in Indonesia, A $39.0 million in the Philippines, and A $23.7 million in Thailand. The difference in costs is proportional to the amount of aflatoxin ingested.

56.7 NATIONAL ESTIMATES OF SALMONELLOSIS COSTS

National estimates of the economic impact of salmonellosis have been reported from countries in Europe and North America since the late 1970s. This has been largely in response to the recognition of this agent as a major cause of foodborne illness in these countries, together with recognition of the association between the human illness and widespread contamination of poultry and poultry products and other meats.

Two studies of the national costs of *Salmonella* infection carried out in the late 1970s were reported from Germany and Canada; estimated annual costs of human illness were DM108 million and Can $84 million respectively.[24,44] These studies presented a detailed analysis of medical and productivity losses but differed in other categories of costs including estimations for some intangible costs such as loss of leisure time and pain and suffering. Both studies estimated further costs of DM131 million and Can $3 million that fell, respectively, on the poultry, cattle, and pork industries in Germany and the poultry industry in Canada. These losses were attributed to the results of *Salmonella* infection in animals or poultry, leading to slaughter, quarantine, or treatment. The German study also presented an analysis of the potential benefits of preventive activities designed to reduce *Salmonella* infection in animals and humans.[44] More recent estimates of human salmonellosis costs in Canada of Can $203 million to Can $846 million and the US of US $0.6 billion to US $3.5 billion indicated the earlier estimates were low.[25,67,93,94]

56.7.1 England and Wales

A detailed study of the costs of salmonellosis was conducted in England and Wales from 1988 to 1989.[80] The aims of the study included the construct of a cost profile of salmonellosis and to provide a basis for estimating national costs that could be used in economic appraisal of preventive strategies. The costs of illness, including direct costs of investigation and treatment of cases, as well as costs to the affected people and their family and lost production from sickness-related absence from work, were obtained via questionnaires completed by individuals with laboratory-confirmed infection and the investigating environmental health officer.

The study identified tangible costs of £1 million (1988 prices) associated with the 1,482 cases in the sample. Public sector costs accounted for 39% of the total, just under half of which was for the investigation of cases. Costs to families and the economy accounted for the remaining 61%. These included production losses associated with sickness-related absence from work that dominated society costs and were more than half of the total costs identified.

To estimate the national burden of disease, the identified costs were extrapolated using the results of a survey that included information about the incidence of gastroenteritis in a randomly selected sample of adults.[52] The results suggested that only one in six people affected consulted a doctor and that only 1 in 38 of all cases was reported centrally. Applying these multiplication factors to the approximately 23,000 reported *Salmonella* cases in 1988 suggested that about 874,000 people were affected, including 149,000 who sought medical treatment and 4,255 cases admitted to a hospital.[79] Costs were related to the severity of illness by using two approaches (see Section 56.4): approach I was based on demand for type of health care;[68] approach II used a severity index that related use of services and length of illness to the patient's subjective appraisal of the number, type, and severity of symptoms.[78,79] Both approaches showed a relationship between the increase in severity of illness and increased use of services and cost of illness.

Total tangible costs estimated for England and Wales in 1988 were £331 million (approach I) and £231 million (approach II) (1988 prices) (Table 56–1). The lower total for approach II reflected the wider range of severity identified and the lower costs per case for the least severely ill. Inclusion of intangible costs would have added a further £32 million to £119 million to these totals. The costs of human *Salmo-*

Next Page

nella infection for England and Wales in 1988 were thus estimated to be between £263 million and £450 million (1988 prices).[79]

56.7.2 Scotland

A large outbreak of salmonellosis in 1981, including 654 cases and 2 deaths arising from consumption of raw milk, cost £1.3 million in direct and indirect costs.[19] This led to a cost-benefit study that recommended mandatory pasteurization of milk that was initiated in Scotland in 1983.[18]

56.7.3 Sweden

In Sweden, 6,043 cases of salmonellosis were reported in 1987 at an estimated cost of US $362,000; 212 of these cases were attributed to eating domestically produced poultry.[58] In a second study, the direct and indirect costs of an estimated 348 domestically acquired *Salmonella* cases arising from poultry, cattle, or swine in 1992 were estimated as SEK 4.9 million (Swedish crowns) (A. Engvall, 1993, personal communication).

56.8 COSTS AND BENEFITS OF PREVENTING FOODBORNE INFECTION

The value of economic appraisal of foodborne disease is three-fold. First, in bringing to public attention an essentially preventable illness; and second, in identifying those areas, particularly in the public sector, that consume resources. The third, and probably most valuable, contribution concerns the economic evaluation of procedures designed to limit or prevent the spread of infection and would include inspection and regulatory activities.

National studies of *Salmonella* infection in Germany, Canada and England and Wales sought to evaluate, through the cost-benefit approach, which particular measure or combination of measures could achieve significant reductions in human salmonellosis. Because of the lack of data relating to some cost categories and reliance on expert opinion in some areas, the value of these studies was to provide a model for looking at costs and benefits rather than provide firm estimates of these. Nevertheless, estimations of the costs and expected success of a number of control measures indicated that, for example, irradiation of poultry meat and hygiene education aimed at both the domestic user and the food service sector would have benefit in reducing infection.

Most preventive activities are related to primary prevention aimed at preventing contaminated food reaching the general public, or secondary prevention aimed at identifying the cause of a problem and eliminating it; for example, when an outbreak of food poisoning occurs.

56.8.1 Primary Prevention

There currently is a need to bring together the critical evaluation of controls to reduce contamination in production processes with economic evaluation of those controls to estimate the potential benefits derived from them. Elimination of contamination early in the food chain would seem controllable and reliable, and therefore desirable, but its real effectiveness only could be calculated if the possibilities for recontamination and human illness were factored in. For example, the incidence of contamination of poultry carcasses exceeds that of the live birds, indicating that cross-contamination during processing is a significant factor in increasing risk of human infection.[50,57]

Even without detailed analyses, general statements on the benefit of a control procedure could be made. For example, although not a cost-benefit analysis, Levy and McIntyre[46] suggested that estimated outbreak costs of US $28,733 resulting from cross-contamination in a restaurant kitchen should be contrasted with the lower costs of primary preventive action such as hygiene education for restaurant food handlers ($500 per course attended by between 20 and 100 people), and regular inspection of the premises by public health officials (US $11 per visit; both at 1973 prices). In 1994, the United States Department of Agriculture (USDA) issued a ruling on mandatory safe handling statements on labeling of raw meat and poultry products.[35] These labels were intended to reduce foodborne illness by advising consumers on safe food handling practices, including thawing raw meat and poultry, cooking raw products, and treatment of leftovers. The cost of a pressure-sensitive label is between 1 and 2.5¢ with about $1,000 to redesign each label to be used in 253,000 food stores in the US. This compares with the cost of illnesses caused by meat and poultry contaminated by bacterial and parasitic pathogens (US $3,880 million to $4,330 million in 1992).[35] However, it would be extremely difficult to estimate the numbers of cases prevented by this approach to measure the actual benefits of the program.

Benefits of prevention probably would accrue over an extended period of time; therefore, any calculation would need to contain not only initial outlay and future maintenance costs, but also the future reduction in cases. On this basis, a measure that was not necessarily cost-beneficial in the first year might become so in time.[107] In 1995, the USDA developed a policy on pathogen reduction through HACCP and used as part of the proposal the economic benefits of HACCP to reduce foodborne disease costs.[36] The benefits accruing from introduction of HACCP systems in meat and poultry processing would be in the range of US $1.9 billion to $171.8 billion over 20 years (see Section 56.3).[23] The range was sensitive to the level of pathogen control achieved. Nevertheless, these benefits would be likely to exceed the costs of implementing and maintaining HACCP systems estimated to cost between US $1.1 and $1.3 billion over the same period.[23] In an alternative approach, the Swedish *Salmonella* control program for poultry, cattle, and swine, including testing animals and feed, sanitary slaughter, hygiene practice, and insurance, was evaluated at SEK 107.5 million in 1992 (Engvall et al., personal communication). This was about 10 times greater than the cost of domestically acquired illness; however, discontinuing the program could cost between SEK 115 to SEK 264 million annually. The success of a measure aimed at preventing, for example, salmonellosis, but that reduced other pathogens and other bacterial contamination would accrue additional benefits.

The desirable level of control or prevention is also a pertinent issue for consideration in developing or evaluating a program; thus eradication of infection in humans or animals may be either impracticable or prohibitively expensive.[32] However, reduction in human illness may be economically a more achievable goal. A German model has been presented where optimum combinations of measures could be expected to achieve a reduction in human illness of up to 65%.[44] This study attempted to identify measures or combinations of measures that would give a positive cost benefit. Given external factors, such as economic constraints on food production and customer tastes and requirements, this approach would allow a certain amount of freedom to choose not only the most cost-effective measures, but also those measures that are most acceptable to the producer or consumer. A Canadian study also took the approach that reduction of levels of poultryborne salmonellosis could be achieved by application of a number of measures.[24] It is necessary to identify those areas where preventive activities are likely to give the greatest benefit in terms of human illness prevented, the effectiveness of the procedure, and the return on investment. One way to achieve this is to measure the economic benefits that arise from specific interventions. Two interventions, with potential widespread application in the food industry and in poultry production, respectively based on postprocessing gamma irradiation to limit the level of contamination of the final product and competitive exclusion (CE) of salmonellosis during poultry production, are considered in Sections 56.9 and 56.10.

56.8.2 Secondary Prevention

The benefits of secondary prevention hardly have been considered at all and, although the scope for action is limited, the potential benefits may be large. These possibilities were explored in a study of a *Salmonella* outbreak attributed to contaminated cheese and in a study of a *Salmonella* outbreak in 1982 from contaminated chocolate.[20,64] The investigation costs of the latter outbreak at the point it was stopped (80% of product recalled) were compared with projected costs of the outbreak had it continued until stocks of the imported product were exhausted. The costs of illness associated with the 245 reported cases, of whom 51 were admitted to the hospital, were calculated to be £504,808 (1982 prices) for medical care, investigation, control, lost productivity, pain and suffering, and recall and destruction of product.[64] If the outbreak had continued until all the imported chocolate bars had been eaten, it was estimated that 36,000 cases would have occurred, 1,200 would have been reported, 230 people would have been hospitalized, and 5 people would have died. The potentially extended outbreak would have cost £1,673,826, over £1 million greater than the actual outbreak. Thus, for every £1 expended on investigation of the illness, there was a saving of £3.50 to the public sector, including outbreak control and medical treatment costs, and £1.50 in lost production. The greatest social and economic savings were for prevention of pain, suffering, and deaths. Benefits not only included the prevention of further illness in the outbreak, but also potential prevention of future outbreaks as a result of corrective measures made to the chocolate production process.

Although this type of economic study is unlikely to be repeated with many outbreak situations, it can be assumed that with a widely distributed contaminated product, intervention by companies and control agencies is justified economically as well as for public health reasons.

56.9 ESTIMATED COSTS AND BENEFITS OF FOOD IRRADIATION

Irradiation of specific foods has been considered by many developing and industrialized countries as an effective process to reduce spoilage and economic loss in harvested products; however, its potential for preventing foodborne illness has not yet been fully realized. Irradiation of specific food substances such as spices and irradiation of food for special "at risk" groups in the population is now common practice. For convenience and safety reasons, astronauts in extended flights have eaten irradiated ready-to-eat foods, and military personnel under field conditions plan to do so.[5,6,66] There also are medical reasons for other groups of people to consume foods with a reduced bacterial content. Hospitals, which provide food for a uniquely "at risk" population, including patients with cancer, acquired immune deficiency syndrome, and other conditions resulting in decreased immunity, are increasingly relying on wholesale suppliers to provide food for patients and staff. Commercial airline catering offers another possibility for provision of ready-to-eat foods that could be irradiated. Food poisoning incidents among airline passengers have been documented at least since 1947.[12,84] Foodborne disease is not a concern only for passengers, but also for crew, and has been considered a leading cause of pilot incapacity, with sufficient documented incidents to justify stringent standards for air-crew meals.[10] The possibility of irradiating the finished products before they are loaded into the aircraft provides an answer to this problem.[60] Other large-scale catering activities that could benefit from product irradiation include catering and centralized production of meals for schools and work canteens, etc. To be cost-effective, these would probably require a centralized large-scale operation with distribution of finished products to many locations. Scotland, England, Canada, and the US have examined the costs of poultry-related disease and the benefits of control procedures, including irradiation of carcasses; in 1997, the US Food and Drug Administration announced it was permitting irradiation of meats including poultry for human consumption.[33]

56.9.1 Poultry Irradiation in the UK

Because of the high capital costs of building and maintaining an irradiation plant and the need to factor in costs of the replacement and disposal of irradiation sources, the approach adopted for assessing benefits has been to calculate accruing benefits over a period of years. For example, a CBA study of poultry irradiation in England and Wales indicated that for 10 regional plants, irradiation of all poultry would have a positive cost benefit accruing over 15 years.[79] The costs of irradiation included the capital costs related to buildings, land, and equipment, and recurrent expenditure associated with overhead and operating expenses. These were modelled in an earlier study of a facility with a throughput of 380 tons per day at an average dose of 3 kGy.[107] Further allowance, in the study of poultry irradiation in England and Wales, was made for additional transport costs to the producer as well as an annual allowance for product promotion. A weighting of 25%, 50%, and 75% of the basic costs was added to incorporate any unforeseen plant and operating costs. The stream of benefits of irradiation (costs of salmonellosis less costs of irradiation) are presented in Table 56–9. These are presented as the net present values (1988 prices) discounted over 15 years, the life expectancy of an irradiation plant, using a weighted range of costs for a series of assumptions about the expected level of reduction in human salmonellosis at a discount value of 5%, the rate recommended by the UK Treasury for the appraisal of public works.[26]

The results indicated that only under the most severe assumptions about irradiation costs and effectiveness, for a 10% reduction in human salmonellosis overall, was the net benefit negative. Thus, benefit was negative only for the highest cost of irradiation (cost +75%) at the lowest assumption for cases avoided (10%). The flow of benefits increased several fold as reductions in human cases increased and were over £1.1 billion if total salmonellosis was reduced by 50%.

56.9.2 Poultry Irradiation in the US

Irradiation of poultry in the US was economically justifiable on the assumption that 81% of chicken carcasses could be irradiated practically, and that no one consuming these would contract campylobacteriosis, and only a few people would be infected with *Salmonella*.[66] However, costs did not include transportation of carcasses, promotion of the process, and removal of the used radioactive cobalt source although a high cost factor associated with deaths was included. These data were updated for the USDA's submission to allow irradiation of poultry in the US.[34] They concluded that the cost of irra-

Table 56–9 Flow of Benefits of Poultry Meat Irradiation Based on a Cost-Benefit Analysis for Irradiation of Poultry Meat in England and Wales over a 15-Year Period[79]

Costs of Irradiation	*Costs of Illness Avoided Minus Costs of Irradiation**		
	Reduction in Salmonellosis		
	10%	*25%*	*50%*
Basic cost	94.5	472.1	1,101.5
Cost +25%	60.6	438.3	1,067.7
Cost +50%	26.8	404.4	1,033.8
Cost +75%	−7.0	370.6	1,000.0

*£ millions (1988 prices).

diation of 0.86¢ to 1.3¢/lb for treatment at 3 kGy would give a positive net public health benefit through savings in medical and productivity costs. This would be in the range of US $35 to $50 million (1991 prices) annually, even if only 10% of the carcasses were irradiated.

56.9.3 Poultry Irradiation in Canada

In Canada, one study showed that complete eradication of *Salmonella* from poultry was not cost-effective no matter what control measure was considered,[32] although another evaluation showed that limited control was more realistic.[25] Here, the costs of human salmonellosis were compared with various control procedures, and it was found that certain operations, such as cleaning crates, use of chlorine in chill water, educational programs, and irradiation were economical, although only the first and last of these were considered 100% effective in destroying *Salmonella* at those particular steps. Control measures also were costed over a 10-year period and annualized to compare with industry and society level costs. In terms of a strict test of effectiveness (90 to 100% reduction in human salmonellosis) and society benefits (US $17.5 million) over irradiation costs (US $17.1 million), irradiation was a viable control measure (costs updated to 1991 US dollars).[95] With fewer illnesses, costs to families and companies also would be reduced for a total benefit of US $28.6 million. The installation and operation costs over the 10-year period were US $14.5 million and $2.6 million for additional labor.

In all these studies, it is assumed that the consumer would pay the extra cost of plant decommissioning, but any obvious price differential between treated and untreated birds could be a discouragement to potential purchasers of the irradiated product. Because the state benefits from saved health costs, subsidies to companies choosing to use irradiation could keep the treated birds competitive in price.

56.9.4 Feed Irradiation

Another approach to reduce the presence of *Salmonella* in chickens was to use irradiated feed. A dose of 10 kGy irradiation increased the cost of by 3¢ per bird.[75] However, even if irradiated feed was the exclusive source of nutrient for broilers, *Salmonella* still would be present on many birds going to the slaughterhouse. Birds raised on irradiated feed probably would be more acceptable to retailers and consumers because no irradiation labeling would be required on the packaging, but less effective in reducing human illness.

56.10 COMPETITIVE EXCLUSION

An alternative approach to irradiation of poultry carcasses to reduce contamination with *Salmonella* would be the use of CE and antibiotics during breeding and rearing of poultry; thus birds would enter the processing plant with lower levels of contamination. This method probably would be less effective than irradiation but more acceptable to the consumer. In

Sweden, elimination of infected flocks, coupled with stringent sanitation procedures, use of pasteurized pelleted feed, and CE have been effective in keeping the infection rate in chickens low, but these measures are 5 times as expensive as the cleaning and disinfecting program used in the UK to control *Salmonella* contamination in poultry, resulting in birds that are more than twice as expensive for the consumer.[58,81,101]

Reducing the number of contaminated birds by CE, although unlikely to be as effective as irradiation, could have an important impact on the levels of human salmonellosis. Policies designed to reduce the numbers of infected birds in breeder flocks and the maintenance of high standards of hygiene at every level of production were credited with bringing about major reductions in numbers of contaminated birds and human infections in Sweden, Denmark, and Switzerland in the 1970s.[87] These policies, largely based on screening and destroying positive flocks and quarantine approaches, may be relatively expensive because of the potentially high level of wastage, particularly in the initial stages, and the need for adequate compensation for farmers to encourage compliance. Adoption of CE potentially could achieve a similar good result but avoid the wastage and cost.

56.10.1 Effectiveness of CE

CE was reported to have reduced *Salmonella* in flocks from 21% to 6.5% in Finland and 24% to 15% in the Netherlands.[81] In Canada, it was considered that CE treatment would reduce human salmonellosis costs associated with poultry by 41%; however, the costs to introduce the program would be greater than the benefits.[25] At 4.1¢/kg for a commercial CE product to be given to chicks throughout Canada, it would cost Can $26.2 million in contrast to the benefits to society, individuals, and industry of Can $22.84 million. Therefore, conflicting reports on the value of CE in reducing salmonellosis may reflect different control strategies in different countries and the acceptable costs per bird to the consumer.

56.10.2 Modelling of CE in England and Wales

In an evaluation of the benefits of a national CE policy in England and Wales, options for reducing *Salmonella* carriage in both breeder and broiler (chicken reared for the table) flocks were compared.[79] These were based on combinations of antibiotic and CE treatment of breeder and broiler flocks. Rather than attempt to estimate the levels of reduction of human *Salmonella* infection that could be achieved, for which little reliable information was available, the level of reduction above which these options would have a positive cost benefit in terms of the number of cases avoided was modelled. Thus, the cost benefits of reducing human infections in the range of 1% to 10% were considered although reductions in human infection as high as 40% or more may be possible.[24] The results of the option appraisal and the flow of benefits based on 1988 prices showed modest reductions of 1% to 5% in human infection could produce a positive net benefit depending on the combination of treatment options.

56.11 CONCLUDING REMARKS

Economic analysis has an important contribution to make in identifying where costs fall, and to the assessment of alternative preventive strategies. The WHO has recognized the importance of such studies and recommends that countries undertake assessment of the economic impact of foodborne disease.[104]

The resources available to invest in preventive activities are, however, likely to be limited. Thus, such activities should be targeted at the factors that have greatest influence, are amenable to modification, and that give the best possible return on investment. Considerable benefits could accrue from preventing poultryborne salmonellosis, and irradiation and CE could make an important contribution to reducing the economic and social effects of this disease. Although irradiation is expensive, its high level of efficiency in reducing contamination could result in a sharp decline in poultryborne salmonellosis if adopted on a large scale. Consumer opposition, however, could delay introduction for a long time to come. In contrast, CE offers a less effective but probably more acceptable alternative that would need to achieve only a modest reduction in human infection to give a positive return on its implementation. Consumers appear to be willing to pay more for safer food, although more research is needed in this area to delineate the conditions under which the shopper would purchase food safety. A study in the US showed that more than half of those interviewed would be willing to pay up to 17 ¢ per pound extra for chickens that are free of foodborne pathogens.[76]

The models presented could be adapted for comparing the relative benefits of alternative approaches to reducing contamination at one particular stage or

Table 56–10 Comparison of the Costs of Major Causes of Morbidity in the US

of intervening at different stages in the production cycle. Such economic analysis of preventive strategies could provide a powerful adjunct to the HACCP approach, which seeks to identify and assess the microbiological hazards and risks associated with food production processes and identify points of control.[43,79] Economic analysis therefore would assist the process of deciding both, at which point intervention provides the greatest benefit and which alternative procedure would be most cost-effective at that point.

The relatively few published studies of the economic evaluation of foodborne disease suggest that the costs are high but that prevention can be economically worthwhile. Most authors indicate the figures they present are underestimates, often based on incomplete data and dependent on assumptions or expert opinion. To provide a more accurate assessment of the costs of foodborne disease, a number of methodological issues need to be addressed. These include the method of approach to costing foodborne illness, the relative contribution and valuation of intangible costs such as loss of life, estimation of levels of under-reporting, and allowance for different degrees of severity of illness. There also may be considerable costs associated with patients who develop long-term sequelae to their original infection. These may last from months to the rest of their life. Little information currently exists on the proportion of cases that develop such sequelae and whether they can be ascribed to a particular incident. Taking account of the numbers of reported and estimated unreported cases and those who develop long-term sequelae, the economic impact of foodborne disease is significant. This is further supported by an analysis of the major costs of meat-associated dietary and infectious disease in the US. Medical costs attributable to meat consumption ranged from US $0.2 to 2.4 billion for gallbladder disease to US $14 to $17.1 billion for diabetes, with foodborne disease, ranked fifth, responsible for US $0.2 to $5.5 billion (Table 56–10).[8]

Bovine spongiform encephalopathy, unfortunately known as "mad cow disease," was discovered in Britain in 1986. Fears that it may be transmissible to man have been discussed widely and considered in the food industry during the last decade. In this chapter, we set out the facts as we understand them up to 1998.

57.1 INTRODUCTION

Transmissible spongiform encephalopathies (TSE) are irreversibly fatal cerebral and cerebellar degenerative diseases affecting animals and man. Various forms are recognized presently over a fairly wide range of animal species (Table 57–1). The clinical presentation of the TSE is characteristic within each host species and the prominent features vary; signs include mental changes with altered temperament, apprehension and nervousness, incoordination with clumsy movements, tremors and unusual posture, changes in sensation and motor control with paresis, and an inexorably progressive and fatal outcome.[81,130] In some forms of the disease in sheep, there is itching (pruritus); the affected animal rubs itself against posts and buildings and the condition has been called "scrapie."

The neuropathological changes in these diseases also have many common features that confirm the diagnosis at autopsy. The hindbrain shows bilaterally symmetrical lesions with spherical or ovoid vacuoles in the grey matter that give stained sections a sponge-like appearance under the microscope (Figure 57–1).

Each of these diseases can be transmitted to another member of the same species by parenteral in-

---

I am greatly indebted to many people for their help. Ray Bradley of the Central Veterinary Laboratory, Weybridge, England, has constantly advised me; he and John Wilesmith have been most generous in giving me information and guidance. I have had further invaluable advice from Dr Richard Kimberlin, Dr D. Matthews, Dr David Taylor, Dr Robert Will, Dr Bill Martin, Dr Jim Hope, Cowan Wilson, John Sloggem, John Watt, Professor James P. Duguid, Eric Allen, Dr Barbara Lund, and my late wife Professor Anne Ferguson. All of the facts are in the public domain, but the views expressed are my own.

jection (eg, intracerebral injection) of homogenate of affected brain, hence the "transmissible" label. Transmissibility across species barriers is discussed later in this chapter.

The discovery of the first known cases of bovine spongiform encephalopathy (BSE) in British cattle in 1986[141] heralded the beginning of a catastrophic outbreak that rapidly caused national and international alarm. The consequences were of major economic importance, affecting farmers, animal breeders, meat producers, and pharmaceutical and other commercial interests related directly or indirectly to bovine products. The grounds for worry extended further into aspects of veterinary, dental, medical, and surgical practice;[142] for example, the source of a significant proportion of nonsynthetic so-called catgut sutures is bovine intestine, and fetal calf serum is widely used for the growth or stabilization of bacterial and viral preparations used in vaccines. Anxieties proliferated into the difficult area of the extensive use of bovine gelatin in confectionery and food production, and into other considerations of materials consumed or used by man that are not directly derived from cows but might have been associated with a bovine item during their production.[51,72,82,100–102,130]

There has been much speculation on the possible hazards of BSE to man, and the relevance of these considerations to food microbiology is clear.[24,52,65,100,126,133] Many informed biomedical and veterinary scientists considered it unlikely that the agent of BSE could be transmitted effectively to man by ingestion of naturally infected meat,[26,119,133,137,148] but there were clamantly expressed opposing views, and not the least of which were those of Professor Richard Lacey and Dr Dealler in England[39–41,43,91] and of Professor Diringer in Germany.[48] A linkage of BSE in cattle with the new variant form of Creutzfeldt-

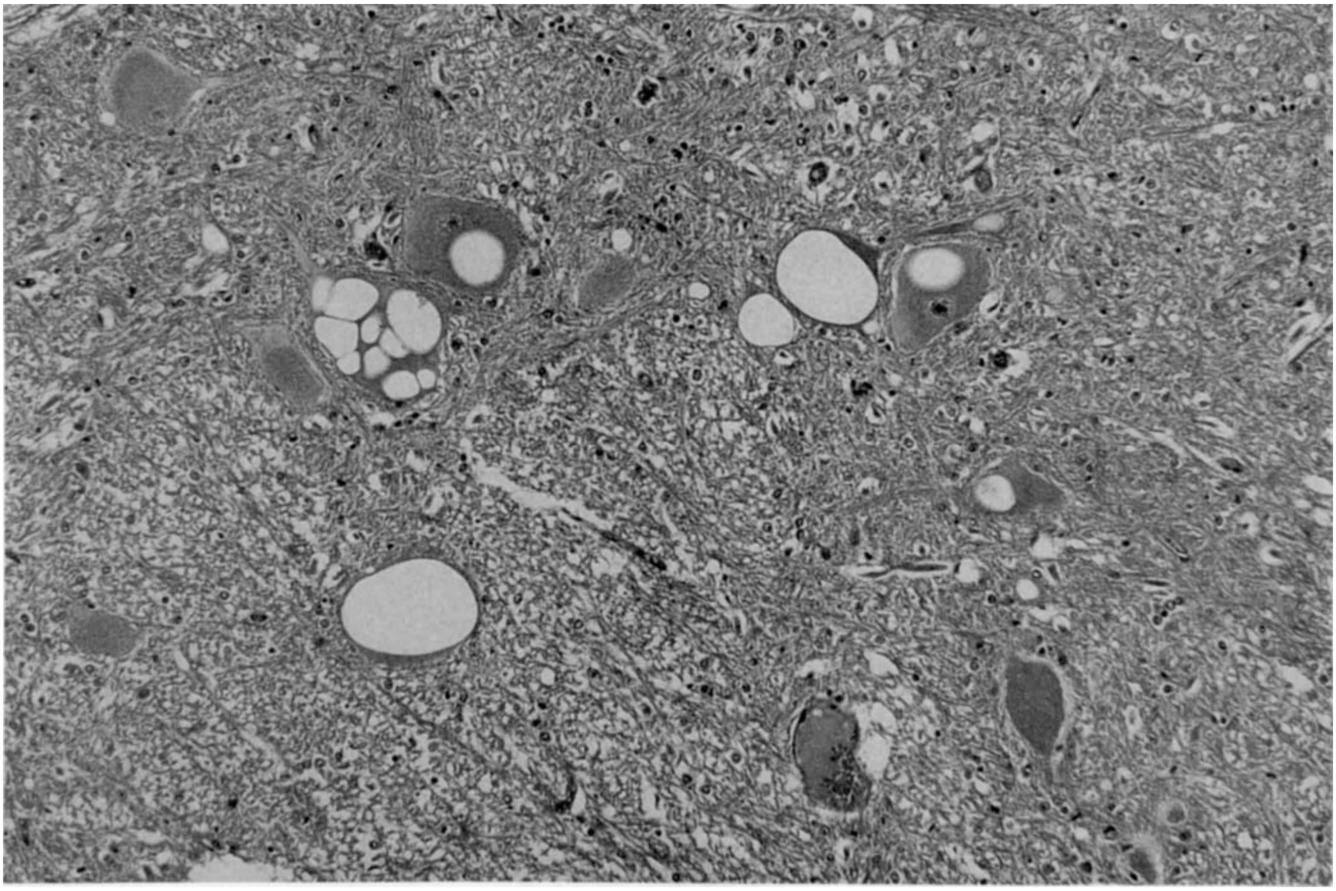

Figure 57–1 Neuronal Vacuolation and Spongiform Changes in the Brain of a Cow with BSE. Haematoxylin and eosin × 560*. Courtesy of S.A.C. Hawkins and R. Bradley.

Jakob disease (nvCJD) in man[150] was suspected[4,61,74] and is now confirmed.[5,20,68] The range of known spongiform encephalopathies of man and animals is considerable. Accordingly, this chapter will focus particularly on BSE in cows, the parallel model of scrapie in sheep, and the spongiform encephalopathies that affect man, notably CJD and kuru. The debated interrelationships of these diseases merit special consideration in the light of some possibly alarmist predictions. In view of the complexity of the arguments involved, some points are made more than once where it is important to establish their connection in this chapter.

57.2 BOVINE SPONGIFORM ENCEPHALOPATHY

Although BSE was first recognized in 1986, retrospective studies showed that some cases of the disease probably occurred in cattle in Britain early in 1985. The epidemic of this apparently new disease then developed progressively to require the destruction of many thousands of cattle in the next 10 years (Figure 57–2, Table 57–2). The data cited by different workers vary a little; this is because the definitive diagnosis of BSE takes some time. The figures given here have been corrected to reflect the numbers of confirmed cases that occurred in a given year rather than those for which notification was received in the year. Figure 57–2 shows how any commentary on the plot of cumulative data should be tempered with observations on the shape of the plot of annual numbers of new confirmed cases.

57.2.1 The Disease

A cow with BSE begins to behave strangely after a mean incubation period of 4 to 5 years from initial

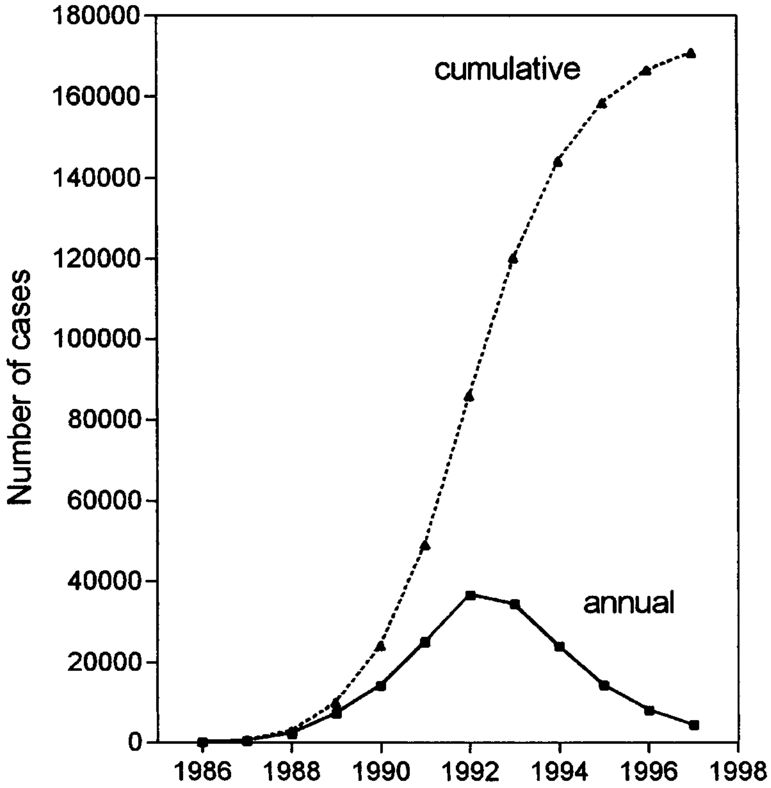

Figure 57–2 Annual Numbers and Cumulative Totals of Confirmed Cases of BSE in the UK, 1986–1997

infection. It licks its nose and grinds its teeth excessively as abnormalities of sensation develop. It becomes apprehensive and is unduly sensitive to touching or to noises. It is nervous when confronted and stands with its head low, its back arched, its feet splayed and stiff, sometimes swaying uncertainly with a wide-based stance and shying up suddenly and unsteadily. Its coordination deteriorates and it stumbles and slips. It is difficult to handle. It shows a fear of doorways that it cannot easily negotiate. It may show cutaneous shivering or trembling of its limbs, and it may become frenzied. It loses condition, appetite, and weight, and reduces its milk production. The duration of the distressing disease is usually a few months from its initial insidious presentation, but the period of illness ranges from less than a month to more than a year until its invariably fatal outcome.

57.2.2 Early Investigations

Very intensive neuropathological and epidemiological studies were set up promptly in the mid-1980s and thereafter by the British authorities responsible for veterinary surveillance.[13,32,45,101,102,130,137,144–147] The early clinicopathological findings indicated striking parallels between BSE in cattle and scrapie in sheep, and epidemiological investigations pointed to proprietary feedstuffs as the likely vehicle of infection of BSE in cows. Subsequent evidence incriminated meat and bone meal (MBM) concentrate in animal feed as the source of the disease. MBM is obtained by the process of "rendering" discarded animal and poultry carcasses and other animal products collected for recovery of their commercially useful constituents (see below). The numbers of sheep in Britain had increased in the 1970s, and scrapie is an endemic disease of sheep in Britain (and many other countries). Hence, the ultimate sources of BSE were assumed to be infected carcasses and offals of sheep carrying the agent of scrapie and, on recycling through the rendering process, offals of cattle infected with the agent. BSE was deemed to be scrapie in cows. This implies that scrapie, long held to be a disease of sheep and goats but not of cows, had somehow broken through a natural "species barrier" that had protected cows for more

Table 57–2 The Annual Occurrence of BSE in British Cattle from 1986*

Year	*Annual Numbers*	*Cumulative Numbers*
1986	63	63
1987	473	536

1997	4312	170682

Up to 26 June, 1998, 171,935 cases have been confirmed on 34,522 farms (confirmed data to mid-1998).

**BSE was not made notifiable until June 1988.*

Source: Data from J. Wilesmith and R. Bradley, Central Veterinary Laboratory, UK, and D. Matthews, MAFF, Tolworth.

than 2 centuries before the events of the 1980s. An alternative possibility, that BSE is primarily a disease of cattle and was unrecognized over the years until the discovery of BSE in 1986, continues to merit consideration. This is discussed later in this chapter.

The initial epidemiological studies[147] revealed that the incubation period for the disease ranged from 2 to 8 years. The modal age of occurrence (and incubation period) is 5 years. The full age range of disease occurrence is now recorded as 20 months to 18 years. Most of the cases were assumed to have been infected as calves. Female cattle have been much more commonly affected than male animals. BSE predominantly hit dairy herds; the disease was much less frequently seen in beef suckler herds. This was attributed to the fact that protein feed supplements are much more commonly used in the management of dairy herds. After sucking colostrum, dairy calves are removed from their mothers and given milk substitute and then weaned on hay and protein supplement. Beef breed calves are suckled with minimum feed supplementation. Indeed, some female cross-bred animals born in dairy herds and taken into beef suckler herds could well have been infected before their transfer and thus account for a significant proportion of BSE cases in suckler herds. The lifetime of a male calf may be relatively short and the numbers of bulls that are allowed to reach maturity are relatively small because artificial insemination is commercially exploited. There are therefore several reasons why the expressed disease was seen predominantly in female cattle in dairy herds.

In general, only one or two animals in any one herd went down with the disease; the occurrence of more than 3 or 4 cases in a herd (mean size 80 animals) was unusual, but some herds were very severely affected. At the beginning of the outbreak, index cases seemed to occur at about the same time at many different farms throughout Britain. As the outbreak developed, the incidence of BSE was highest in farms in the south and east of England and lowest in Scotland, with no early cases in Ireland. The initial pattern of occurrence of the disease suggested that there was a common source that was widely distributed, that we were observing an "extended common source epidemic," and there was little doubt that the infective challenge had been delivered in the ruminant-derived protein feed supplements supplied from rendering plants. The possibility that subtoxic levels of organo-phosphorus compounds used in farming are involved as direct factors or indirect cofactors in BSE has been largely discounted, but still is being researched.

The likely period when the cows first were challenged with the agent of BSE in this way was the winter of 1981–1982. It is important to appreciate the range and the detailed nature of the early studies instituted immediately after the disease was recognized in 1986. By December 1987, findings based on thorough investigation of the first 200 affected herds were as follows.

1. BSE is not simply genetic in origin. A genetic predisposition in cattle has been considered,[143] but no breed disposition has been noted among the cattle affected by BSE.[76,130,145,146]
2. BSE is not attributable to a recognized chemical toxin.
3. BSE is not associated with the use of an identified vaccine or other commercial biological preparation.

In the latter part of 1988, it was shown by Fraser et al. that BSE is transmissible to mice.[55]

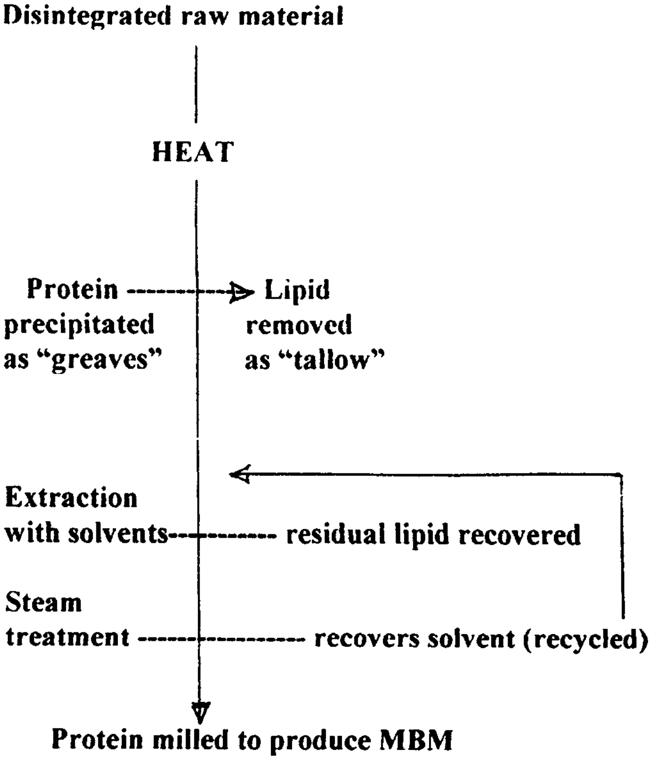
A working party on BSE, set up in 1988 under the chairmanship of Professor Sir Richard Southwood, produced the Southwood Report in February 1989.[119] The British government already had made BSE a notifiable disease (June 1988) and, in the next month, introduced a temporary ban on the supply of ruminant-derived protein for ruminant feed supplements following studies by Wilesmith published in 1988.[147] The Southwood Committee then recommended in-definite continuation of the ban. Further studies by Wilesmith and Bradley and their collaborators were published in 1991–1993.[13,144–147]

57.2.3 The BSE Agent

The transmissible agent has not been visualized definitively and does not have the characteristics of a bacterium or a conventional virus. In its pathogenesis and in its resistance (in preparations of homogenates of infected brain) to chemicals, heat, and radiation, it behaves like the scrapie agent and these features are described in more detail below.

57.2.4 A Note on Rendering

Animal carcasses and waste animal material are rendered into commercially useful MBM by various processes that include heating to remove water and to liberate fat (Figure 57–3). A detailed survey of all 46 rendering plants in the United Kingdom (UK) by Wilesmith and his colleagues[145] in 1988 is very informative. The raw material included fat trimmings, bones, offal, whole carcasses, and other mixed material. The sources were bovine, ovine, porcine, poultry, and others. The initial products are liquid fats (tallow) and the separated protein-rich residual solids are called greaves; the latter can be further processed to yield MBM. Most of the plants used batch processing, but 13 plants had more modern continuous systems. Essentially, the raw materials are broken down mechanically to an acceptable particle size (ranging from 1 cm to 10 cm) and then heat treated at temperatures ranging from less than 100° C to 150° C. The periods of exposure to the maximum temperature for each of the processes studied varied widely.



Disintegrated raw material
HEAT
Protein precipitated as "greaves"
Lipid removed as "tallow"
Extraction with solvents
residual lipid recovered
Steam treatment
recovers solvent (recycled)
Protein milled to produce MBM

Figure 57–3 An Outline of the Rendering Process

An important change had occurred in the late 1970s and early 1980s. The processing of greaves traditionally had included a hydrocarbon solvent treatment at about 70° C for 8 hours to increase the extraction of tallow by treatment with hydrocarbon solvents such as benzene, petroleum, hexane, perchlorethylene, or trichlorethylene. The protein meal produced in this way had a very low fat content. Residual solvent finally was removed from the solid product by heating and by exposure to pressurized steam (live steam stripping). As the market for tallow declined and, simultaneously, as the fire and explosion hazards of the hydrocarbon extraction processes were recognized and safety measures were more stringently enforced, the hydrocarbon solvent treatment and extraction steps were omitted by many processing plants. Thus, the fat content of the MBM produced by these plants, or by processors using their material, was increased significantly. The protective effect of fat for microorganisms is well known. When the solvent extraction procedure was used, it may have assisted decontamination because the second (solvent recovery) heat step took place in a relatively low fat environment. At the time of the 1988 survey, the only two plants using solvent extraction were in Scotland, and they produced most of the MBM made in Scotland in 1988. The rapid reduction in the use of the solvent step by English producers during the period 1977 to 1982, and hence the great increase in the proportion of unextracted MBM made available for use as cattle feed supplements, is dramatically evident in the data produced by the Wilesmith team.[145] Bear in mind that it is thought that the initial BSE challenges were delivered to British cattle in 1981–1982. If the exclusion of the solvent step (and the loss of the additional heat-treatment involved in solvent removal) had nothing to do with the apparent boost in the challenges assumed to have been delivered in the late 1970s and early 1980s, this must be a remarkable coincidence. However, some reviewers indicate reservations and suggest that changes in rendering procedures began much earlier—in the early 1960s.

57.3 SCRAPIE

This fatal cerebral degenerative disease of sheep and goats was recognized in western Europe in the early 18th century. Countries in which the disease has occurred in sheep in the last two centuries include England and Wales, Scotland, Spain, Germany, Hungary, France, Italy, Switzerland, The Netherlands, Iceland, Cyprus, and Norway.[130] In some of these countries, the disease is endemic (enzootic). In others, it has arisen in imported sheep. It has been kept out of Australia and New Zealand by a policy of quarantine followed by compulsory slaughter of affected imported sheep and flockmates, with due compensation. Scrapie has also occurred in North America, southern Africa, India, and Japan. Countries now apparently free from scrapie include Australia, New Zealand, Denmark, Argentina, and Uruguay.[130]

57.3.1 The Disease

Scrapie most commonly affects breeding ewes aged 2 to 4 years and presents as loss of coordination affecting the hind limbs. Disordered sensation commonly, but not invariably, gives rise to itching. The animals then scrape themselves against walls, gates, posts, and trees so that there is patchy loss of wool with lesions developing in the underlying skin. Scrapie follows an inexorably fatal course; affected sheep gradually go down and die after several weeks or months. The histopathology of scrapie is that of a spongiform encephalopathy. There is no inflammatory cell reaction and there is no antibody response.

Scrapie is transmissible to sheep by parenteral injection of infected brain. The incubation period varies from about 5 months to 5 years, depending on the strain of scrapie agent concerned and the genetics of the recipient sheep. The influence of the host genotype on the course of the disease is of special interest. The disease in sheep (and in goats) can be transmitted to mice, but this is not invariably successful. Intensive studies of scrapie in mice have yielded much valuable information, including the finding that more than 20 different strains of the scrapie agent can be characterized and the fact that host genetic control of the experimental disease can be demonstrated with different strains of mice.[46,81,82]

57.3.2 The Scrapie Agent

When it was shown in 1936 that scrapie is a transmissible infection, scientists began a long and difficult search for the elusive causative organism. It became clear that this was not a metabolic, chemical, parasitic, protozoal, or bacterial disease and, in due course, scrapie was assumed to be a viral infection. In view of its long incubation period in sheep, it was regarded as a "slow infection"—a term introduced by Sigurdsson to embrace various diseases that typically had long incubation periods. The evolution of the concept and the development of the notion of the unconventional agent of scrapie, because its nature and debated taxonomy continued to puzzle investigators, is brilliantly described by Kimberlin.[81]

The terms *viroid*, *virino*, and *prion* were coined successively to take account of evolving views, and the validity of these terms was contested fiercely. In late 1998, the scrapie agent are generally regarded as a prion as originally conceived by Stanley Prusiner in 1982.[112–115] A prion is a proteinaceous infectious particle apparently devoid of nucleic acid. Prions, as defined, are detectable in the high infectivity fraction of brain homogenate from mice experimentally infected with scrapie from sheep. Prion theory is still debated.[22,54,95]

Why is the scrapie agent not thought to be a bacterium or a conventional virus? The infectivity of affected brain homogenate passes through bacteriological filters of very small pore size (eg, 50 *n*m and perhaps much smaller). It is unusually resistant to destruction by heat, by antimicrobial chemicals, and by ultraviolet or ionizing radiation. For example, the infectivity of brain homogenate is not lost after it has been boiled in water and it is not assuredly destroyed by standard sterilizing exposures to wet heat, such as autoclaving at 121° C for 15 minutes; exposure to 134° C to 138° C for 18 minutes in a porous load cycle may achieve inactivation, but this sometimes is inadequate. It is partially inactivated by phenol but not by alcohol or by strong disinfectants such as formaldehyde or glutaraldehyde. Exposure to 2% available chlorine as sodium hypochlorite for 1 hour may be effective, but sodium hydroxide is not assuredly inactivating.[135,136]

No causative organism can be visualized in stained preparations under the light microscope. The agent has apparently not been visualized by electron microscopy (EM); however, in negatively stained EM preparations of detergent extracts of affected brain treated with protease (proteinase K), abnormal scrapie-associated fibrils (SAF) occur. These are long strands of material composed of an abnormal form of host glycoprotein called prion protein (PrP). The normal (cellular) form is designated PrP^C and is present in normal brain cells and other neurones; the modified form in scrapie is designated PrP^{Sc}. The latter is resistant to digestion by proteinase and is not altered by treatment with enzymes that hydrolyze or modify nucleic acids. PrP^C can be digested by proteinase K, but the relatively resistant scrapie isoform PrP^{Sc} undergoes limited hydrolysis of the N-terminal amino acids to yield a product referred to as PrP27–30. The term PrP^{res} has been introduced as a general term for such abnormal (resistant) PrP. According to Prusiner, a prion rod (SAF) is an aggregate of prions composed virtually entirely of PrP27–30 molecules. Thus, detergent extraction and limited proteolysis of scrapie-infected brain containing PrP^{Sc} yields fibrils visible by negative staining in the electron microscope. These can be studied also in scrapie-infected spleens[122] or in central nervous tissue from cows with BSE (Figure 57–4). When SAF are purified, there is some copurification of infectivity so that the infectivity titer is increased, and it is possible that scrapie-associated fibrils of modified PrP are indeed the infectious agent. Bear in mind, however, that experienced laboratory workers describe the agent of scrapie as very sticky; accordingly, it might stick to an aggregate and copurify with it.[122,128] Moreover, opinions on SAF are divided and some workers hold that these may be artifacts produced when the infected material (such as brain or spleen) is processed for EM. Abnormal PrP is not seen as fibrils in stained sections of infected tissue, but one must allow for the greater magnification and resolution of the electron microscope. The abnormal PrP that can be visualized by immunostaining is not directly correlated with infectivity, and PrP^{res} with apparently no infectivity can be generated.[3]

The transmissible agent of scrapie has been cultured in some experimental studies but has not been cultured effectively in any system. It can be passed experimentally from sheep to sheep and goats,[109] from goats to mice, and from sheep to mice and hamsters, causing typical patterns of disease in these animals. It can be passed also to rats and cattle.[57,130] Many biologically different strains are characterized by the pathogenesis of the disease observed in mice. Some of the strains can mutate. In this context, Kimberlin has posed the critical questions: If the scrapie agent is a virus or a virino, we need to find the scrapie-specific nucleic acid that has eluded us so far. If scrapie is caused by a prion devoid of nucleic acid, and if prion theory holds sway, how do we account for the observed scrapie strain variation and mutation in sheep and in experimentally infected mice? Some microbiologists still find it difficult to accept that this can be achieved without a nucleic acid component. For example, Asher[8] and the Addendum to Chapter 6 of the Spongiform Encephalopathy Advisory Committee's Report of 1994[130] indicate reservations that are held. Some virologists maintain that nucleic acid would be detectable by more modern methods, but they have not produced proof of their view so far. Alper[6] brought biophysical evidence to support the view that the agent is devoid of nucleic acid and is derived from domains of nerve cell plasma membrane lacking normal PrP molecules. The debate continues and this was reviewed by Manuelidis in 1997.[97]

It is not absolutely clear that there is direct vertical (ie, transplacental) transmission of scrapie, but there is a fair amount of indirect evidence suggesting that prenatal or perinatal infection can occur. The maternal transmission of scrapie in sheep, from ewe to lamb, is said to be common but is attributed largely to infection of the lamb at birth from contaminated placenta. The latter also accounts for lateral transmission to other sheep by consumption of placenta (by adult sheep[109]) or by pasture contamination. The survival and persistence of infective prions in soil have been demonstrated. It seems that mites harbor scrapie prions in affected pastures,[158] but the significance of this is not clear. The incidence of scrapie in the offspring of the flock at lambing time increases in proportion to the time that lambs are held and allowed to run with their ewes.[81] Ridley and Baker[121] questioned the whole concept of maternal transmission of spongiform encephalopathy, but there is now evidence suggesting that some maternal or perinatal transmission of BSE occurs at a relatively low level,[7] say 10% under experimental conditions and perhaps about 1% under field conditions. This still is debated.

Much work done by Dickinson and his team at Edinburgh has afforded insight into the complex genetics of host susceptibility to scrapie in sheep[46] and to strain variation and mechanisms of pathogenicity of the scrapie agent.[47] The pioneering work was developed further by Kimberlin and colleagues.[84] The length of the incubation period of scrapie is dictated by the aggressiveness of the strain of infecting agent and the genotype of the host. The *Sip* gene (scrapie incubation period gene, with two alleles sA and pA) influences resistance and hence the incubation period in sheep. Homozygotes for sA are the most susceptible to natural scrapie, and sheep homozygous

for pA have been shown to be much less susceptible to experimental scrapie. The *Sip* gene in sheep is probably the same as the *PrP* gene (discussed elsewhere in this chapter). Paradoxically, sApA heterozygotes are susceptible to experimental scrapie but apparently not susceptible to natural scrapie. These considerations have practical value in developing relatively resistant flocks, but a word of caution should be added. If the *Sip* gene in sheep acts as the analogous *Sinc* gene in mice, Kimberlin points out that ewes of a resistant *Sip* genotype could be healthy carriers of disease and a potential source of danger to their lambs and other sheep of a susceptible genotype. Similarly, a *Sip* mutation in the host animal could probably derepress the susceptibility mechanism (or switch off the resistance mechanism) to allow disease to be expressed; and a mutation in the carried noninvasive strain of scrapie could change it to a neuroinvasive strain.[81–83] These are speculative theories that merit continuing consideration in relation to various models of disease presented by the spongiform encephalopathies.

57.4 TRANSMISSIBLE SPONGIFORM ENCEPHALOPATHIES IN OTHER ANIMALS

TSE of commercially reared (ranch-bred) mink, transmissible mink encephalopathy (TME), was first recognized in Wisconsin in 1947 and has been attributed to the feeding of scrapie-contaminated tissue.[21,66] The high mortality of TME is notable in some of the outbreaks, with no apparent secondary spread unless cannibalism occurs. Infection is assumed to have been solely by ingestion, although bite wounds and scratches are common in these animals; bites sustained when feeding could be a more effective route.[133] The ingestion of untreated abattoir waste and dead stock possibly contaminated with scrapie prions in mink feed is likely to be the factor associated with high challenge doses of the infecting agent.[21,82]

In the late 1970s and early 1980s, a chronic wasting disease of captive mule deer and elk, with the features of a TSE, was reported in the United States (US).[154,155] The affected animals either had been reared or held for some years in captivity, but more recent findings indicate that cases of chronic wasting disease have occurred in free-ranging elk and deer in the US and that lateral transmission may occur by direct contact or as a result of environmental contamination.[156]

BSE-like disease has occurred during the last decade in 19 captive exotic ruminants of seven different species in Britain up to mid-1998[86,87,130] (Ray Bradley and Dr. D. Matthews, personal communications). The source of the infection in the early cases has been assumed to be the ruminant-derived protein feed supplements that caused the outbreak in cattle. Some of the affected exotic ruminants were born after the ruminant feed ban. It seems that some exotic species are particularly susceptible and that lateral and possibly maternal transmission of the disease may have occurred in some cases, but it is also possible that infected feed was fed unknowingly to them, as it was to some cattle, after the ban.

In 1990, spongiform encephalopathy was discovered in domestic cats in Britain. By mid-1998, 85 cases of the feline disease (FSE) had been confirmed in British mainland cats. Most of these cats were aged 5 to 6 years when affected. The annual numbers of cases from 1990 to 1997 were 16, 11, 13, 10, 14, 8, 6, and 6. Only one cat with FSE was born after the extension of the offal feed ban to include pet foods; the evidence points to a feed source, with BSE rather than scrapie as the most likely origin. FSE was reported in a cat in Norway in 1995. There has been one case also in Northern Ireland and one in Liechtenstein. The agent of FSE has now been shown to be identical with that of BSE.[20] FSE also was reported and confirmed in several captive large cats (nine cheetahs, three pumas, one tiger, and two ocelots at mid-1998) born in British zoos. These animals had been fed raw cattle carcasses and had eaten infected brain or central nervous tissue. In 1990, the experimental transmission of BSE to pigs was reported.[38] Transmission was achieved by parenteral inoculation of very large doses; this model bears no resemblance to any likely natural challenge. The disease has not been transmitted to pigs following challenge by feeding; this study is not yet quite complete, but it is now longer than 8 years postchallenge.

57.5 MODELS OF HUMAN PRION DISEASES

Despite the world's long experience of scrapie in sheep, there is no evidence that the scrapie agent has caused disease in man. Why, then, should we be considering scrapie and other animal models in such detail in a chapter concerning the possible risk of foodborne BSE to man? The reason is that there are many parallels between scrapie in sheep and BSE in cows, and there are now debated connections between these diseases and the known spongiform encephalopathies of man that include kuru (a disease affecting the Fore tribe in Papua, New Guinea) and CJD. Very substantial evidence reviewed by Kimberlin and others[81] indicated that CJD and its previously known variants up to 1995 were not epidemiologically linked to scrapie. Thus, although BSE may be a form of bovine scrapie, CJD in man did not seem to be human scrapie—unless a theory proposed by Diringer[48] gains currency.

57.5.1 Kuru

The investigation of an unusual disease occasionally provides clues to mechanisms of wide biomedical interest. So it was with this disease that affected the people of the South Fore highlands in Papua, New Guinea. The story is told by Gajdusek and Zigas,[56] who traveled to the Fore region in 1955. At that time and into the 1960s, kuru accounted for many deaths, predominantly of women and young children, among the South Fore natives.

Early signs of the disease included unsteadiness and poor coordination with clumsy movements; there was cerebral and especially cerebellar dysfunction. The course of the disease ranged from several months to 1 to 2 years in adults, and it progressed more rapidly in children. It was invariably fatal and virtually took middle-aged and older women out of the population.[56,114]

The infection was linked to the native practice of ritual cannibalism associated with mourning ceremonies for relatives within the tribe (endocannibalism). The distribution of the disease was attributed to the fact that women and young children ate the brains and offal, whereas the men ate the muscle. Whether the agent of kuru might be transmitted by routes other than by ingestion—such as contamination of the eyes or abraded skin or mucous membranes—is still debated because part of the mourning ceremony included smearing remains on the bodies of the mourners.

Gajdusek suggested that the original source of infection may have been a sporadic case of CJD that died in the tribe at the turn of the century and was subjected to the ritual; the infection then would have been recycled progressively through the relatively small population of the South Fore people. The neuropathology is that of a typical spongiform encephalopathy with degenerative vacuolar lesions in the brain and cerebellum and with no inflammatory reaction, but with PrP-positive and amyloid-positive kuru plaques. Cannibalism was stopped in the mid-1950s and was followed by a clear reduction in cases among younger children and a steady advance in the age of onset of the disease as the slow fuse burned out in the community. The long incubation period of 20 to 40 or more years for adults accounts for cases occurring into the present decade, but no South Fore native born after 1959 has developed kuru. The disease is disappearing.[114]

It seems that a direct route of infection was essential for the expression of kuru, with no secondary cases. Studies of the disease in children and mothers have shown no evidence of prenatal, perinatal, or neonatal infection transmitted from mother to child; thus, transplacental infection or infection by ingestion of human milk does not seem to have occurred.

Kuru is transmissible by intracerebral inoculation to apes and monkeys. Early attempts at per-oral transmission failed, most probably because of inadequate dosage, but also perhaps because intragastric intubation was used (Dr C.J. Gibbs, personal communication). Successful oral transmission to monkeys with primate-passaged brain was achieved later.[58]

57.5.2 Creutzfeldt-Jakob Disease

This is a spongiform encephalopathy of man with a worldwide distribution and an incidence of about 1 in 1 to 2 million people annually. Some known clusters of cases, for example in Sephardic Jews of Libyan descent and in a relatively inbred community in Slovakia, are attributed to a genetically linked susceptibility.

There are three known forms of CJD.

1. ***Sporadic CJD*** is presumably caused by a spontaneous somatic mutation in the *PrP* gene with the production in the host of the abnormal form of PrP, or by a chance transformation of the normal protein to an abnormal protease-resistant self-replicating form, or it may be the result of a mutation in a silent (latent carried) strain of the CJD agent that changes to neurovirulence. Sporadic CJD accounts for about 85% of cases.
2. ***Inherited*** or familial (genetically determined) CJD is associated with germ-line mutations of varying penetrance that predispose the person to CJD. This accounts for 12% to 15% of cases.
3. ***Iatrogenic CJD*** results from the injection or implantation of hormones or tissue, or a surgical device contaminated with material from a human case or carrier of CJD. Examples of iatrogenic infection include cases attributed to contaminated electroencephalogram electrode implantation, contaminated neurosurgical instruments, implantation of infected dura mater, a corneal transplantation, and injections of human growth hormone or human gonadotrophin derived from human pituitary glands. The accounts of the iatrogenic transmission of the CJD agent are well established in the literature and have been reviewed comprehensively by Prusiner.[114]

Note: Previously recognized clinical variants of CJD occur as the Gerstmann-Sträussler-Scheinker syndrome and fatal familial insomnia. These are not further discussed in this chapter.

It has been difficult to accept at face value the observations of sporadic CJD on the possible development of endogenous CJD by mutation of a host gene (see, for example, discussion by Johnson[79]), for this challenges our accepted dogma in relation to infection. If a sporadic form of a potentially infectious disease can arise de novo in a new host, we would have to accept that Needham's long-debunked views on spontaneous generation merit rehabilitation. Kimberlin suggests a way out.[81] He theorizes that CJD may exist in latent silent form as a widespread infection of man and that this is maintained in the population, largely without expression of the disease. On rare occasions, there might be a spontaneous mutation to neurovirulence in an unfortunate host and this would ultimately give rise to a sporadic case of CJD. Perhaps undue genetically determined susceptibility would account for the higher frequency of familial cases in this model. At present, we lack sufficiently sensitive detection methods for CJD to test this concept of the occurrence of pathogenic and nonpathogenic or host-repressed strains. The postmortem diagnosis of CJD rests on the histopathological evidence and on the identification of abnormal PrP^{Sc} (or PrP^{CJD}) by partial purification of infected brain homogenate and extraction to yield material for an immunoblotting procedure with anti-PrP sera, by a dot blot procedure, or a histoblotting technique after prior proteinase digestion and chemical denaturation.

Prusiner has considered the molecular genetics of inherited human prion diseases with much care. He paraphrases the Kimberlin theory of a putative latent agent in a worldwide reservoir of humans and links this with the views of Chesebro on PrP and the scrapie agent.[22] Thus, he seemed to be driving us to the view that there may be a common prion lying latent in most of us. The development of CJD is a rare, random event (excluding the iatrogenic routes), whereas almost everyone with *PrP* point mutations or inserts appears eventually to develop neurological dysfunction. An exception is mutation at codon 200, which has only 50% penetrance. Prusiner referred ominously to a worldwide pool of potentially dangerous prions that may occur in humans, animals, and insects without causing detectable illness. He was moderately reassuring about possible foodborne challenges, making the point then that there was no evidence to support the hypothesis that sporadic CJD could be attributed to prions being ubiquitous in our food chain; and he observed that infection by the oral route is extremely inefficient in the hamster model. He did not dismiss the possibility that CJD may arise spontaneously and endogenously without any exogenous prion source, and he considered that somatic mutation of the *PrP* gene is a likely mechanism. He did not favor the notion of a ubiquitous virus that is somehow switched on when the *PrP* gene codes for a mutant protein that facilitates the expression of CJD infection. In Prusiner's view, the prion can achieve all of this, given the right circumstances, without the help of viral nucleic acid. As the prion diseases stand apart from conventional virology, Prusiner asked us to consider them as pseudoinfections that do not obey rules that we have previously laid down in our textbooks.

The resistance of the transmissible agent of CJD is comparable with that of the scrapie agent. Accordingly, special precautions must be taken in dealing with tissues that might contain the CJD agent and in the subsequent use or disposal of any potentially contaminated instruments. In the UK, the Advisory Committee on Dangerous Pathogens has issued guidance on precautions that should be observed.[1] It is of interest that Dr D.W. Burdon of Birmingham, England, studied a very resistant agent occurring in human ileal fluid that he named ileal-fluid dependent organism (IFDO) in the 1980s.[50] This had some properties in common with CJD agent, but there are differences.[129] Whether the IFDO agent is an organism in the accepted sense or a replicating crystalline form derived from the medium is uncertain. Awareness of such a phenomenon is important at a time when there is a strenuous search for prion-like agents in human tissues. Meanwhile, Collinge and his colleagues[29,30] have pointed out that screening of selected patients by *PrP* gene analysis may reveal that sporadic CJD has been underdiagnosed by current clinical and histopathological methods. These observations have a bearing on our surveillance of BSE-like disease in man in the coming decades and indicate the need for caution in interpretation until we have reliable markers for the causative agents of transmissible prion diseases.

Fears that BSE may be linked to CJD were increased in the mid-1990s by reports of CJD-like conditions affecting young people in the UK. With the exception of possible iatrogenic cases, sporadic CJD rarely affects people before the age of 30, but two cases of CJD and one CJD-like illness affecting three British teenagers reported in Britain in 1995[118] attracted the attention of the media (eg, *World in Action,* independent television program, UK, 14 August 1995). Three cases of CJD occurred in relatively young patients aged 19, 23, and 27 in Warsaw over a period of only a few years when the authorities were monitoring another form of brain disease. In recent years, there were separate reports of sporadic CJD affecting three British dairy farmers with one or more confirmed cases of BSE in their herds.[37,124,127] This was more than might be expected, although the occupational denominator used must affect the calculation. A fourth case of CJD disease in a beef farmer was reported in October 1995.[159] Some understandable alarm was expressed[4,61] and some moderation urged.[107] When associations were sought between CJD and the occupation of those affected, vicars and professional drivers also had a slightly higher experience of sporadic CJD than would be expected,[118,127] but the dangers of drawing conclusions from very small numbers were acknowledged. Significantly, when the agents from farmers who had had BSE cases in their herds were subsequently strain-typed, the strains affecting the farmers were not the same as the BSE agent.

CJD is not more common in abattoir workers, sheep farmers, veterinary surgeons, or butchers. If the BSE agent is the cause of sporadic CJD, these people could have been exposed occupationally to potentially infective tissues and would seem to be more at risk than dairy farmers. Evidence from the European Community surveillance project shows no differential increase in the risk of sporadic CJD to farmers in the UK resulting from possible occupational contact with BSE.[44] For example, between 1992 and 1994, there were three cases in British farmers, four in French farmers, two cases in Germany in a single year, and three in Italy in one year. If there is any link between BSE in cows and a CJD-like syndrome in dairy farmers, it might be reasonable to ask how the challenge that hit the cows might also have hit their close attendants. Would drinking unpasteurized milk merit consideration? This does not seem reasonable; there is no evidence of any infectivity whatsoever in transmission studies of milk from affected cows. The airborne route of infection or the contamination of wounds with dust from protein-supplemented cattle feed might merit investigation among those who milled MBM in the 1970s and early 1980s, if only to put another speculation to rest. It has been suggested that dairy farmers sometimes chew cattle-cake and might have ingested the agent in MBM concentrate. Pig and poultry farmers have not developed CJD although feed for these species would have contained more MBM concentrate than cattle feed when it was used. On present evidence, we have found no link between BSE and sporadic CJD. We must note that CJD seems to have a slight predilection for farmers, even in countries that have little or no BSE,[118] while those farmers who had BSE-infected cows and who contracted CJD in recent years in the UK did not yield an agent at postmortem with the characteristic profile of the BSE agent.

The theory that the whole problem of BSE in cows and BSE-like syndromes in their attendants can be attributed to organophosphate applications (used on sheep and cattle to control various infestations) is not generally regarded as tenable, but this view of Mark Purdey[116] was given considerable prominence in a September 1995 television program in the UK, and speculative suggestions that a toxic cofactor might be involved in BSE continue to be raised—but without persuasive evidence so far.

Despite the generally documented view that the agents of scrapie and BSE do not share common ground with the agent(s) of CJD, Diringer[48] considered that a link between scrapie and CJD is likely to exist. He reiterated the point that primary transmission of scrapie from sheep to cattle is likely to escape conventional histopathological diagnosis.[34] Diringer speculated that sporadic cases of CJD may arise in man indirectly as a result of passage of the scrapie agent from sheep through cattle to man, while a familial form of CJD (CJD_{200}) arises by a primary route *directly* from sheep in family members genetically predisposed to the disease because of an inherited mutation altering codon 200. He ascribed the rarity of expressed disease in man to the need for a two-hit situation in CJD_{200}—the genetic defect and the chance encounter with the agent—coupled with the 50% penetrance of the mutation, and the rare transmission of scrapie from sheep to another intermediate host (the cow, for example). He maintains that primary transmissions differ in clinical symptoms and histopathology from secondary transmissions and have longer incubation periods.

Strangely, we have not yet formally tested the general assumption that BSE was scrapie-derived by experimentally challenging cows in the UK with a range of scrapie strains. The technical problems were outlined by Collee and Bradley,[27] but there are pressing reasons to ask why such a study has been delayed for so long. The experimental primary transmission of scrapie to American cattle, reported by Clark and colleagues in the US,[23] resulted in a different form of BSE from that seen in the UK. According to Diringer, this is because the UK disease was caused by recycling, hence representing secondary transmission from BSE-infected material. He maintains that sporadic CJD and CJD_{200} are always due to transmission from animals to man and present with severe dementia as the predominant and early characteristic. On the other hand, he says, kuru and growth-hormone-derived CJD present with cerebellar signs of ataxia because "these two forms of disease are known to be caused by secondary transmission of the agent." He regards sporadic CJD as coming from sheep via cattle but, as it would then come as a primary transmission to man, he would accord BSE in man the clinical presentation of a primary infection. He uses the term *virus* for the transmissible agent involved.[49] It will be argued that, if Diringer's model has any validity, the outbreak of BSE in Britain has seen the possibility of a much more frequent oral transmission of the BSE agent to man in the 1980s so that sporadic cases of CJD will become more common.

In developing his theory here, the term *primary transmission* is used to denote that a new species is challenged, and *secondary transmission* to mean that the recently acquired agent is passed on within the same species. Thus man's first encounter with an animal-derived agent is primary and man-to-man passage of a recently animal-derived agent is secondary. (In the context of these slow infections, we shall have to define *recently* in the light of our continuing experience.)

Professor Diringer maintains that sporadic CJD and CJD_{200} are always due to primary transmission from animals to man and have severe dementia as the predominant and early characteristic. Until recently, the only known reservoir has been scrapie-infected sheep (and goats). He postulates that sporadic cases of CJD have resulted from passage of the scrapie agent from sheep to man—an extremely rare event in the general population. Now, with the advent of the UK outbreak of BSE, there is another candidate primary route—from sheep via cattle to man. The agent may have been modified by a period of secondary transmission within the bovine species during which Diringer suggests that the agent has "adopted a multipotent property of infection" as witnessed by its extended pathogenicity to exotic ungulates and members of the cat family and to some laboratory animals. He draws parallels with primary transmission across a species barrier with unadapted virus strains and secondary transmission within a species with adapted strains of viruses.

According to Professor Diringer, the scrapie agent in sheep hardly ever leads directly to disease in man, except in those with the codon 200 mutation, but the adapted agent in cattle is now capable of causing disease in other species, unconstrained by genetics. Diringer's theory implies that all humans, rather than only the genetically susceptible, could develop CJD when they encounter the bovine-adapted agent. In fact, the scrapie agent can be experimentally transmitted to many different species, more than the BSE agent at the time of writing. The BSE agent has transmitted naturally to a wider range of species than has the scrapie agent, but this is attributable to the common feed source of the BSE agent and thus delivery (in MBM or in infected carcass meat) to cattle, cats, large cats in zoos, and some exotic captive ungulates.

(*Note:* The possibility remains that BSE could have been transmitted back to sheep in infected MBM, but we have no present evidence.[27])

When CJD occurs as an iatrogenic infection following direct inoculation or implantation into the central nervous system (CNS), the syndrome is indistinguishable from sporadic CJD with progressive cerebral cortical dysfunction and dementia. Challenges delivered by a peripheral route, as in the repeated intramuscular injection of infected human cadaver-derived pituitary hormones used to treat growth defects,[18] resulted in progressive cerebellar ataxia akin to the clinical presentation of kuru. Accordingly, it was argued that if BSE caused a CJD-like syndrome in man as a result of ingestion or noncerebral parenteral implantation or injection, this would be a peripherally delivered challenge and a cerebellar syndrome, as in kuru (see below), might be the more probable presentation.[118,130] The cases of CJD-like disease in farmers and teenagers that attracted attention in 1995 in the UK did not present as cerebellar syndromes; this was thought to be reassuring.[130] However, according to Diringer's theory, the clinical presentation of BSE in man would not present as a cerebellar syndrome, and dementia would be the predominant clinical picture. In the event, the cases of new variant CJD that have been recognized to date typically presented with early psychiatric problems (see below).

57.5.3 The New Variant (nvCJD)

In March 1996, the CJD Surveillance Unit at Edinburgh reported that they had observed a (temporal) cluster of a new variant CJD syndrome (V-CJD, or nvCJD to denote new-variant disease) affecting 10 British patients aged less than 42 years (mean 27 years), with dates of onset of illness within the previous 2 years.[150] The nvCJD cases presented with early behavioral signs that were superseded after some months by progressive neurological dysfunction with ataxia and involuntary movements, and then there was progressive dementia with a clinical course ranging from more than 6 months to more than 22 months. There was thus a psychiatric presentation and a relatively prolonged CJD-like illness before death. The patients did not show the typical EEG findings of conventional CJD, but the histopathology of the brain showed spongiform changes and extensive abnormal PrP plaques. The psychiatric and neurological features now have been documented carefully.[161,162] The Spongiform Encephalopathy Advisory Committee (SEAC) stressed at that time that there was no evidence to link nvCJD with BSE, but in the absence of a credible alternative, the most likely explanation was that these cases were linked to exposure to BSE before the introduction of the ban on Specified Bovine Offals (SBO) of 1988–1989 that prohibited the use in products for human consumption of those tissues considered most likely to contain the infective agent. By the end of 1998, 38 definite or probable cases of nvCJD had occurred in Britain, plus 1 in France, and a link between nvCJD and BSE had been established by groups of workers using different approaches.[5,20,28,31,68] By the end of March 1999, a total of 39 deaths in the UK were attributed to nvCJD.

Lasmézas and colleagues in France successfully transmitted BSE to macaque monkeys in 1996.[92] The finding by Collinge and his coworkers in London in 1996[28,31] that different prion strains produce characteristic patterns of abnormal prion protein glycoforms on Western blots added to the growing body of evidence linking BSE with nvCJD. Preparations of prion protein from the brains of patients with nvCJD showed glycoform patterns similar to those seen in preparations from cows and other species with BSE and different from those seen with sporadic or iatrogenic CJD. These findings were developed further by the London team in parallel studies with transgenic mice expressing the human *PrP* gene and in nontransgenic mice. The results were published in October 1997.[68] The evidence that the agent of nvCJD is distinct from those of sporadic or iatrogenic CJD is compelling. Moreover, the glycoform profiles of the nvCJD and BSE agents are virtually identical, and there were striking similarities in the clinical presentations of the diseases that the two agents produced in mice and in the observed (histopathological) deposition of PrP in the brain. Minor differences between the two agents noted in transmission studies probably reflect a species barrier effect with the inbred mice used in these experiments; for example, nvCJD transmitted more readily than BSE to the human transgenic series.

The crucial clinching evidence of Moira Bruce and colleagues at Edinburgh, also published in October 1997,[20] "make implausible any assertion that all of these observations (of a link between BSE and nvCJD) are coincidental."[5] Transmission studies were done with material from six typical cases of sporadic CJD (spCJD) and three cases of nvCJD. The results were compared with the Edinburgh team's extensive experience of the "signatures" of a range of TSE strains in strain-typing experiments based on the incubation periods and pathology observed in panels of inbred mouse strains. Mice injected with material from the nvCJD cases developed a progressive clinical disease very similar to that produced by the BSE agent (at the lower end of the incubation period range for BSE and related isolates). Moreover, the lesion profiles for the nvCJD series—the patterns of vacuolar degeneration produced in the brains of the test mice—were those characteristic of the BSE agent. The team concluded that they now have "strong evidence that the same strain of agent is involved in nvCJD and BSE." Their strain-typing studies also showed that the same agent is responsible for FSE and for the TSEs seen in exotic ruminants in the UK. It is important that the agent of nvCJD can now be distinguished from that of spCJD and that the CJD illnesses studied in the two dairy farmers were of spCJD type and not nvCJD. Thus, while nvCJD is linked to BSE, the disease seen in the dairy farmers is not linked to BSE.

57.6 DISPUTED INTER-RELATIONSHIPS

Several important questions arise from the earlier kuru and CJD studies. Are the agents of CJD and kuru related to the agents of scrapie and/or BSE? These agents all cause what we have come to regard as prion diseases, but it is essential to be aware of the presently recognized domains of their inter-relationships. Thus, the agents of sporadic CJD and kuru may be closely related (if not identical), and the agents of scrapie and BSE seem to be closely related, although the BSE agent has a unique biological profile. A reassuring division seemed to separate the CJD/kuru complex from the scrapie/BSE complex; this is being further tested by comparing the biological characters in mice of agents isolated from recent and historical cases of CJD.[20]

The separation of CJD and scrapie is essentially based on epidemiological findings. There is much evidence (reviewed by Kimberlin[81] and simply summarized by Taylor[133]) to show that a country's experience of scrapie is unrelated to the numbers of cases of CJD that occur in its population. CJD has a worldwide distribution, but scrapie (and BSE) does not occur in Australia or New Zealand. It might be argued that CJD in Australia or New Zealand has its origins in the Old World, and that continuing immigration accounts for its continuing occurrence so that the

Next Page

absence of scrapie in Australasia may not be so significant in that part of the argument as it might seem. Moreover, Diringer's view is that we cannot rely on much of the epidemiological evidence of the past that seems to separate CJD from scrapie. He cites an 1883 report of scrapie in a cow[123] as evidence that this primary transmission from sheep to cow may have been happening for at least a century, and he considers that this is likely to escape conventional histopathological diagnosis.

Despite intensive surveys, there is no recorded occupational hazard for the development of CJD, for example in sheep farmers, butchers, veterinary surgeons, cooks, or abattoir workers. False correlations have been drawn with the eating of sheep's eyes by a group of Jews of Libyan descent living in Israel (who actually have a genetic predisposition to the inherited form of CJD). Foods with a doubtful association have included black puddings and veal and venison, but these seem to join the list of several possible red herrings that statistical manipulations tend to throw up one year and reject the next when the data depend on personal and family recollections of dietary preferences of relatively small numbers of cases.[118] The possible association with veal or venison merits continued surveillance, while bearing in mind caveats regarding the analysis of data based on dietary histories (for example, the apparent incrimination of liver consumption in the US that is not now regarded as significant).

Is BSE really scrapie in cows? The circumstantial evidence linking the agent of BSE to that of scrapie is persuasive. The infection that led to the outbreak of BSE is calculated to have had its beginning in the late 1970s or early 1980s, just when the rendering process for the production of ruminant-derived protein feed supplements was changed. It is reasonable to assume that high-challenge doses of the scrapie agent were thus allowed to be distributed to cows and calves in the UK. We know that oral challenge is an inefficient route of infection for the prion diseases. The significant changes in the rendering process included the omission of the organic solvent step and the reduction of one of the heating stages. The relatively short incubation periods of the BSE-like illnesses that affected some of the captive exotic ungulate animals subsequently fed with protein supplements in Britain suggest that these animals are unduly susceptible. Perhaps cows in the UK are particularly susceptible at a critical stage in their development as calves, but note that there are definitely adult-exposure cases in cattle, although calfhood exposure predominates (oldest case 18 years old).

When a breakthrough infection occurred in cows, there was recycling of rejected bovine carcasses and offals before BSE was recognized as a specific disease and the bovine-adapted strain would be selected and sequentially passaged. This would have increased the exposure of cattle to the agent and, theoretically, would be likely to increase its virulence (aggressiveness, neuroinvasiveness) for cows, although there is no evidence for this. The cycle would not be broken until the disease was recognized in 1986 and the facts established in the late 1980s. When appropriate steps were taken in 1988 (ruminant feed ban) and 1990 (SBO ban for animals) and a suitable time elapsed for these to take effect, the numbers of infections in younger animals began to diminish progressively by age class (in the mid-1990s). The bans were not as effective as they should have been at the beginning; they have been progressively enforced so that numbers of cases in cattle born after the 1988 ban (BABs) also continue to diminish.[70,111,130] These reassuring trends reflect parallel experience on a much more extended time scale with kuru, but bear in mind that the ancestry of the agents of kuru and CJD seems to be different from that of BSE and scrapie, as discussed.

It may be argued that BSE is not scrapie in cows but that it has always been a bovine disease unrecognized until the circumstances of the present outbreak brought it to light. The BSE agent has very much in common with the scrapie agents, but it has some characteristics of its own. It can be transmitted to sheep and causes a disease resembling scrapie. When it is transmitted to mice, it produces a typical syndrome, but attempts to transmit it to hamsters have been so far unsuccessful (Dr James Hope, personal communication). When a scrapie agent from sheep in the US was parenterally injected into cows, the resultant disease was "distinctly different from BSE,"[34,57,104] but Kimberlin has pointed out that the American strain of scrapie agent used was not representative of the scrapie strains likely to exist in many of the different breeds of sheep in the UK.[83] Moreover, Diringer[48] holds that the UK strain of BSE is a secondary bovine-adapted strain and thus differs from a (primary) scrapie strain. An important observation is that all of the BSE isolates from cows in Great Britain (and even Switzerland) produce a uniform pattern of disease when subjected to a standardized mouse bioassay. Whereas we can characterize many different strains of scrapie on the basis of their different incubation periods and slightly different pathogenesis and neuropathology in mice (under standard conditions), BSE isolates from cows have similar characteristics in mice regardless of the geographical location of the cattle or the year in which the agent was isolated. Thus, the BSE agent has a profile of its own that "breeds true" in cows and sets it apart from previously identified strains of the scrapie agent. Furthermore, the strain characteristics of TSE agents from domestic cats, a nyala, and a greater kudu and from a pig, sheep, and goat with experimental BSE are indistinguishable from the "UK BSE agent," despite these different species having different *PrP* gene sequences.[20] This does not break the postulated link between scrapie and BSE. If the BSE agent evolved in the cow from the ovine scrapie agent, the continuing selective pressure of passage in the new host species would ensure the emergence of a mutant (bovine-adapted) strain with a relatively short incubation period, and this would then dominate. Kimberlin has shown how this happens with a hamster model and the selection of a mutant strain of scrapie (263K).[83] Nevertheless, the possibility that BSE was not recently scrapie-derived is still a valid option.

If BSE existed in cows before the present outbreak made us aware of it, the clinically expressed disease presumably was uncommon. Wijeratne and Curnow[143] drew our attention in 1990 to the observations of Young and colleagues in 1983.[160] These workers reported that 4.3% of 10,458 animals culled from 24,800 cows in 80 Friesian dairy herds were removed because of their "undesirable temperament." Is this a further clue to what might have been happening in our herds before the 1980s when BSE was recognized? These animals did not show other signs of BSE, and many factors influence temperament in animals (and humans). Moreover, if a relatively avirulent endemic (enzootic) strain of BSE existed undetected in the past, it is presumably still with us in our herds across the world. Despite all of the increased awareness of BSE and worldwide surveillance of the last decade, there is no supporting evidence for this, but Marsh,[98] the SEAC,[130] and others[110] note that there may be a rare subclinical form of TSE in cattle in the US. See also Rampton and Stauber's more recent claims.[117] In the US, the Food and Drug Administration (FDA) was relatively late (mid-1997) in banning the use of slaughtered animal products (all animal protein except pure pork or pure horse) from cattle feedstuffs. The US livestock industry has had a voluntary ban in place since 1996; this official ruling is a delayed but wise precaution, although it does not appear to extend to pet food or to chicken or pig feedstuffs. Debated interrelationships here again merit concern. Cross-contamination in mills and feed stores from the latter sources may have been an important element in prolonging the UK experience of BSE. Collee and Bradley observed in 1997 that mammalian MBM was not completely withdrawn from UK farms until August 1996.[27] In view of the large amounts of MBM exported until 1990 from the UK and destined for pig and poultry feedstuffs abroad, and considering the large numbers of breeding cattle exported from 1985 to 1990 before controls operated, it is surprising that more cases of BSE have not been reported from mainland Europe and elsewhere abroad.

57.7 BASIC PRINCIPLES

How can we explain the story so far? Let us develop an argument from basic principles, while conceding that the agents of the prion diseases seem to break some of the generally accepted rules of microbiology. The production of an infection depends on the transmission of an adequate challenge dose of the infecting agent by an effective route into a susceptible host. Factors that then influence the outcome include the virulence or aggressiveness of the pathogen and the resistance or relative immunity of the host. Although some orally transmitted microbial infections can be established by a relatively small challenge dose of less than 100 organisms, as in bacillary dysentery or typhoid fever, several of the typical so-called food-poisoning infections (and intoxications) depend on a prior multiplication stage in food to deliver a very high challenge dose of bacteria or bacterial toxins. There are clear exceptions to this generalization; for example, extremely low numbers of some food-poisoning salmonellae caused a nationwide outbreak of disease principally affecting children in Germany in 1993.[94] In this context, note that very small challenge doses of salmonellae in chocolate or cheese (dietary items rich in lipid) are known to be effective on occasion. It is thought that this may be linked to protection of the infective agent by dehydration during processing and investment in a protective lipid envelope (Professor J.P. Duguid, personal communication). The quantity and the quality of the pathogen are thus important considerations in the development of a successful challenge, but susceptibility factors in the host are also of great importance, and the physico-chemical nature of the vehicle may be crucial. Bear in mind that the altered rendering process for the production of MBM for cattle allowed much more lipid to be present in the mix.

Our knowledge of quantitative aspects of orally delivered enteropathogenic or neuropathogenic viruses is inadequate and we have few models to guide us; however, our evolving knowledge of the prion challenge associated with kuru (in which secondary cases do not seem to have occurred) might allow us some insight in assessing the potential hazard of BSE as a possible foodborne infection for man. Again, Prusiner's caution to regard prion diseases as "pseudoinfections" and to beware of the limitations of conventional terminology and concepts is timely and must be taken seriously in this discussion. Moreover, we must again note that the CJD/kuru complex (with man as the natural host) still should be regarded as separate from the scrapie/BSE complex, unless Diringer's argument holds.

There is presently evidence that prions observe some rules of specificity and there are clear experimental examples of species specificity in the molecular biology of prion disease. Consider the de novo synthesis of prions in an experimentally challenged transgenic mouse, chimaeric for the donor and recipient host species—for example, a mouse with human and mouse *PrP* gene sequences. When this mouse is challenged with either mouse or human infectivity prions, the incoming prion selects the PrP of the donor type to convert to the abnormal PrP isoform; thus, the challenge prions seek out their own species PrP in this experimental model. Prions thus appear to carry information that predetermines the nature of the prions that they cause to replicate in a susceptible host. However, after serial passage in successive hosts of the same species, specific prions of scrapie seem to become adapted so that a standardized dose can produce a reproducible disease syndrome with a set incubation period in laboratory mice (though this may be influenced by the genotype of the host, which can moderate degrees of susceptibility).

Difficulties in transmitting experimental scrapie and BSE to various animal species indicate that species barriers operate.[130] The apparently high susceptibility of the captive exotic ungulates, especially the greater kudu, that went down with BSE in Britain, suggests that these animals are particularly vulnerable, or that they were challenged in a way that is unduly effective. As various species were affected, it seems likely that the nature (quantity and quality) and the mode of challenge were important factors. More species were similarly exposed but did not succumb. The kudu group seems to have been extremely susceptible, with possible lateral spread of the infection; this remained unproven in 1998, but it has led to speculation that there may have been an African link with the origin of BSE in the UK. Although spongiform encephalopathy has been recognized in wild and captive deer and elk in the US, I am unable to trace any record of BSE-like disease in native African animals.

The promptly effective control of the FSE outbreak in domestic cats in the early 1990s clearly suggests that the cat food manufacturers were quick to appreciate the problem and to exclude a suspected ingredient. We do not know if the absence of reported TSE in dogs reflects another particularly effective (canine) species barrier or whether the differences between commercially produced dog food and cat food are crucial in this respect.

The fact that, in general, only a few cows in any one herd have been affected by BSE is difficult to explain, although microbiologists and infectious disease physicians are well acquainted with the phenomenon in relation to diseases as different as meningococcal meningitis, pneumococcal pneumonia, and poliomyelitis in which carrier rates may be very high while apparently sporadic cases of the expressed disease occur during an outbreak. Explanations for such a hit-or-miss pattern of expressed infectious disease usually include considerations of variable genetic resistance, an unequal distribution of the challenging organism, changes to virulence that may occur within the host, failure of specific immune mechanisms in individual cases, and a compromised state that lowers the specific or nonspecific defenses of an unfortunate victim. In the transmission of BSE from contaminated feed to an occasional cow, having excluded genetic predisposition as a major factor, it seems likely that the challenge dose (in its unusually resistant form) was very unevenly distributed in the supplement given to a herd. It may be that the time of challenge of a calf is critical and that the agent could perhaps have a better chance of reaching its target if the permeability of the animal's gut is still in a relatively immature state. It might be that the weaning diet occasionally could damage the gut and allow a challenge access at a critical time or that a microbial infection or a chemical agent depressed natural defenses. It may be that the challenge dose was very small and was delivered over a prolonged period (say, from the late 1970s until the late 1980s, when the feed ban was introduced), so that one or other of these cofactors had to operate to produce the disease. And it may be that a small but potentially effective challenge might be associated with such a prolonged incubation period that the animal died or was killed before the disease was expressed. Considerations such as these allow innumerable speculations at this stage in our ignorance of the key mechanism of infection in BSE. Bear in mind that the evidence of many experimental models of prion disease indicates that the oral route is inefficient, but experience with the agents of kuru and other diseases in animals shows that a very high oral challenge dose can be effective.[58] (Although it is generally thought that kuru was transmitted orally in the Fore people, some writers reserve the possibility that the ritual smearing of remains of the deceased on the skin and around the eyes of the mourners, particularly the children, may have been the significant route of infection.) The most likely explanation for the low within-herd incidence of BSE is that there was low average exposure of the cows to "packets" of infectivity that were widely spaced early in the epidemic, reached a peak until controls became effective, and are now declining to zero.[85]

Is it possible that when BSE occurs in one animal in a herd, all of the cows have actually acquired the agent in a low-grade, unexpressed form that may smolder in the whole herd? The concept of a temporary carrier state is valid for diseases such as poliomyelitis and pneumococcal pneumonia. The carriage of the organism at some location in the host quickly wanes if the disease is not expressed. In some diseases, such as typhoid, a chronic carrier state may develop in a patient who has survived the expressed disease. But a more insidious form of prolonged subclinical infection, termed latency, is seen with herpes virus infections and some other viral diseases. Here, the infecting agent becomes integrated into host cells and has the capacity to replicate and emerge from latency to produce disease when circumstances alter the host's ability to hold it in check. Professor Lacey[91] has developed an argument along these lines for BSE, but we have no evidence for this. With regard to lateral spread, we do not seem to have any evidence for excretion of the BSE agent from noncalving infected cows, whether affected or not. The situation in sheep scrapie is different.

Kimberlin and others entertain the possibility that a very low-dose challenge with BSE in cows may have a very extended incubation period, so that the real mortality is not likely to be revealed because most cows are not allowed to live long enough for the full picture to emerge. Lacey has joined up a series of the above speculations to produce his doomsday scenario; some of the links in his logic are vulnerable, but they may be redeemed by Diringer.[48] The estimates developed by Dr Dealler[39,41] assume that perhaps 700,000 undiagnosed BSE-infected cattle went into our food chain before our control measures were effective. We urgently need a more sensitive assay system to investigate each of the theories further, and we must meanwhile preserve a rational objectivity. If the change in rendering practices with noninactivation of prions in MBM does not seem to be the entire reason for the start of the outbreak in cattle, it may be that the effective oral dose in ungulates needs to be at a critical level and that partial inactivation in the past has been enough to avoid clinical disease. When a combination of recycling of infected carcasses and modified rendering brought together very high-challenge doses and significantly lower inactivation, the critical level of challenge may have occurred in the packets of infectivity that we envisage in MBM.

A worrying feature of the species barrier is that a prion disease affecting species A that cannot be transmitted to species B may be established successfully in species C and then, after passage to species C, may possibly be transmissible to species B. Thus, it is important in the control of the potential hazard of BSE for man that we do everything possible to suppress the disease in cattle and in any other species. The ban on ruminant-derived protein substances in food destined for cattle in 1988, the compulsory slaughter and complete destruction of BSE suspect cattle, and the ban on the use of SBO in human food in 1989 and its extension in September 1990 to apply to food for all animals and birds in the UK were major steps toward safety in this context. The lesson should be further explained to any countries that do not yet see the writing on the wall, and the message to scientists working with BSE in experimental animals must be very clear.[1] European countries are well informed of the British experience via the European Commission. Other countries are informed on animal health matters by the Office International des Epizooties and on public health by the World Health Organization.[101,102] Although BSE has not been reported in the US, the authorities there are well informed,[8,110] but the source of TME merits further investigation there,[98,130] the feeding of ruminant-derived protein to cattle should certainly be banned (this happened in the latter part of 1997), and increased surveillance of "downer" cows will be a wise precaution. Meanwhile, for very important economic reasons, Argentina, Australia, New Zealand, and many other interested countries are maintaining their vigilance.

Prusiner considers that the species barrier is determined by the degree of difference between the amino acid sequence of the PrP of the donor species (the challenging prion) and that of the recipient species.[115] The closer the resemblance, the more likely it is that the prion disease will be transmissible. Bovine and ovine PrP differ at 7 positions, whereas bovine and human PrP differ at more than 30 positions. He argues that the likelihood of transmission from cows to man must accordingly be low, but he adds a cautious afterthought. It may be that some areas of the PrP molecule are more important than others in terms of their sensitivity or resistance to the induced conformational change that produces the abnormal form. Thus, there may be critical hot spots, perhaps near the center of the PrP molecule, where similarity of amino acid sequence reduces the efficacy of the species barrier. These considerations have become even more complicated with the finding that helper molecules made by the host may hinder or assist refolding of the PrP molecule. Almond[4] looks less optimistically at this aspect of cross-species transmission. He cites the work of Scott and coworkers[125] and holds that the bovine *PrP* gene sequence is slightly closer to the human sequence than is the sheep sequence, and the apparently important 96 to 167 region has only five differences as compared with six.

57.8 WHAT HAS BEEN DONE TO BRING THE UK CATTLE OUTBREAK OF BSE UNDER CONTROL?

The short answer is a great deal, but some of the legislation was not enforced quickly enough. Recognition of the disease in 1986, followed by good communications between the veterinary authorities and cattle breeders and an immense amount of investigative work in Britain, led to general awareness of the situation and some inspired retrospective analyses. BSE was made notifiable in June 1988. An initially inadequate compensation scheme was introduced, and the terms were subsequently improved. Compulsory and controlled slaughter of all animals with suspected BSE was arranged, and the laboratory confirmation of all suspect cases was organized. A ban on the use of milk from affected animals was introduced and instructions for the safe disposal of carcasses were issued. Orders were issued to control possible infective hazards during the calving of parturient suspect cows isolated on approved premises and with disposal of placentas and bedding by incineration and burial and with disinfection before reuse of the premises. More effective preventive measures were needed. On August 15, 1995, a new SBO order imposed further restrictions with the compulsory staining and disposal of specified bovine offal. Significantly, skulls may not be opened to remove brains and eyes; there are now restrictions on the mechanical recovery of meat from vertebrae,[27] and bovine meat on the bone (and bone marrow) are banned as from December 16, 1997.

A remarkably comprehensive investigation into possible sources of the outbreak of BSE was set up in the early days. In the first instance, this explored theoretical causes across an enormously wide range from chemical poisons and trace element deficiencies to genetic diseases and vaccine reactions. The evidence incriminating ruminant-derived protein in animal feed supplements was sifted and collated painstakingly, with many cautions and provisos underlining the scientific care of those involved in interpreting the clues. All of this was done efficiently, despite unappreciative and sometimes ill-informed and alarmist comments in the press. Official action followed a rational course that has been held firmly [(see the Spongiform Encephalopathy Advisory Committee's Interim Report on Research (1992)[129] and the Progress Reports of the Ministry of Agriculture, Fisheries and Food (1995)].[111] A summary of the early steps is given in Table 57–3.

Investigations have continued and special efforts have been made to evaluate the gradual success of the ban on the use of ruminant-derived protein supplements in animal feed and to extend the search for other risk factors that might suggest other supplementary routes of infection.[71,129,130] Some unconfirmed cases of clinically suspect BSE in cattle may be attributable to other diseases; these are under surveillance.[140] The media have been vigilant in asking pointed questions and getting authoritative answers;[73] there has been a considerable amount of irresponsible reporting, and there has been some evident reluctance to put all of the facts on the table. However, it is difficult to understand or to accept all of the charges of official silence and inadequacy,[91] although the management and control measures could have been better at some critical stages.

57.9 WILL THINGS NOW GET WORSE FOR THE COWS?

In 1991, I set out the likely course simply as follows[25] on the basis of data and predictions published by several experts. If the pattern of disease originally recorded by Wilesmith and the Southwood Working Party is followed, most cases of BSE will occur in cows that were infected as calves in 1987 and 1988

Table 57–3 Early Official UK Action Taken To Monitor and Control BSE

Date	*Action*
November 1986:	BSE recognized and histologically confirmed in a British cow.
November 1987:	Occurrence of new disease of BSE reported by Wells and colleagues in the *Veterinary Record.*
May 1988:	Working Party on BSE set up under Professor Sir Richard Southwood to examine, report, and advise on implications for animal and possible human health hazards.
June 1988:	BSE made notifiable in Britain.
July 1988:	Ban on sale or supply of ruminant-derived protein for feeding to ruminants (Ruminant feed ban).
August 1988:	All clinically suspect animals to be slaughtered; carcasses to be destroyed; 50% compensation paid.
December 1988:	Milk from suspect animals to be destroyed.
February 1989:	All recommendations of Southwood Report acted upon.
June 1989:	Consultative Committee reports on research needs.
November 1989*:	Ban on sale for human consumption of specified bovine offals in which the BSE agent might occur (Specified Offals ban). (Note: Offals from calves aged less than 6 months were initially exempted from this ban. In June 1994, the ban was extended to include intestine and thymus from calves aged less than 6 months.)
February 1990:	Compensation for slaughter of suspect animals increased from 50% to 100%.
April 1990:	New Spongiform Encephalopathy Advisory Committee (SEAC) set up under Dr David Tyrrell to advise the British Ministry of Agriculture, Fisheries and Food, and the Department of Health.
September 1990:	Specified bovine offals ban extended to embrace all animal feed and poultry and bird feed as well as human food.
October 1990:	Cattle farmers to keep records of all calves born, and the identities of the dams.
July 1991:	Export controls imposed on specified bovine offals (SBO).
November 1991:	Ban on use of SBO for production of fertilizers.
August 1995:	SBO Order imposed further controls on specified bovine offals.

*Dates for equivalent orders in Scotland and Northern Ireland are slightly different.

and will develop signs of illness 3 to 5 years later, say 1990 to 1993. The numbers of cases of BSE greatly exceeded those originally forecast by the Southwood Working Party,[119] presumably because of the recycling that occurred before the feed ban was introduced; this could not be taken into account by the Southwood predictions because the amount of recycling could not be estimated. The numbers of confirmed cases peaked in 1992 to 1993 as Wilesmith predicted, with substantial decreases through 1994 and into 1995. On the basis of continuing advice and surveillance, I then wrote in 1993[26] that cases of BSE infected in 1987 to 1988 (before the ban) will be clinically evident in the years 1989 through 1995 or beyond, but most will have occurred by 1994 and 1995; there would be many cases after the average 4- to 5-year incubation period had passed and allowances would have to be made for cases that could occur from contaminated feed that was already in the pipeline when the ban was imposed in 1988. This, and other intentional or inadvertent slippage, accounts for many cases that could arise in animals younger than 4 years old in 1993 (ie, animals born after the 1988 ban on the sale or supply of ruminant-derived protein feed supplements).

With hindsight, it would have been wise to combine the ban on the sale, supply, or use of these supplements with rigorous steps to ensure that cross-contamination of other feedstuffs could not occur and that contaminated feedstuff in the pipeline or in store on site was identified and destroyed. Subsequent legislation has gone some considerable way to close various loopholes in this regard. Substantial numbers of BABs developed BSE (Table 57–4); up to June 1, 1997, 32,767 were confirmed. By the end of 1998, the number had risen to 37,987. Most of these had presumably ingested ruminant feed protein supplement. The numbers affected are considerable and the annual occurrence of these cases would be expected to reflect a mean incubation period of about 4 to 5 years, with a decreasing chance of infection for each annual cohort as the controls became more effective. Thus, we might expect a major decrease in the numbers of BAB cases of BSE in calves born, say, after 1994. At this stage, it is too early to cheer. The evidence that there is occasional vertical (ie, maternal) transmission of BSE from a cow to its calf complicates the picture, and the possibility that lateral (ie, horizontal) infection may rarely occur (from one animal to another by contact or by environmental contamination) is still entertained though unproven. Although it is possible that BSE is occasionally transmitted maternally or horizontally,[7,130] the indications are fairly clear that these events are not occurring sufficiently often to sustain the present outbreak. If feed is the only significant source of infection (and no other source has so far been identified in a very extensive research program), and if current controls really are applied, it is expected that the numbers of new confirmed cases of BSE will continue to decline. The data available in mid-1998, when this review was completed, support this prediction, but it has to be admitted that some cows with early signs of BSE were being missed before the controls were reviewed and tightened in the mid-1990s. With this in mind, for example, Hoinville and colleagues in 1995 took account of unidentifiable infected animals that had been culled before they exhibited clinical signs of BSE.[71] Stekel and colleagues[132] have predicted future numbers of cases of BSE in cattle (Table 57–5).

Table 57–4 Confirmed Cases of BSE in Cattle Born after the July 18, 1988 Feed Ban, by Date of Birth

Year of Birth	*Number of Cases*
1988 (after July 18)	11,917
1989	12,578
1990	5,535
1991	4,279
1992	2,417
1993	1,121
1994	142
1995	3

(From data available up to January 1, 1999 [37,987 cases])

Source: Data from *MAFF Progress Report*, December 1998.

The crucial factor in reducing the numbers of further cases (BABs), which already may be quite numerous, is the exclusion from the animal food chain of tissues known to contain the BSE agent in infected cattle. Collee and Bradley[27] summarized anxieties relating to the industry's carelessness and evasion and delays in appreciating some of the hazards of cross-contamination of animal feedstuffs; as late as mid-1994, it was estimated that about half of the specified bovine offal materials being processed were not separated properly and could still have been entering rendering plants. The Meat Hygiene Service was set up in early 1995 to make the UK controls more effective. There was much to do. Table 57–6 shows the new measures that were introduced from late 1995 to 1998.

Confirmed cases of BSE in cows born after the mid-July ban in 1988 were worryingly numerous. The data given in Table 57–4 must be interpreted with caution because the deaths of all of the cattle born in a particular year and destined to die of BSE

Table 57–5 Predicted Numbers of Cases of BSE in Cattle in Great Britain

Year	*Predicted Numbers of BSE Cases (Low and High Estimates)*
1995	13,880–16,110
1996	8,050–11,270
1997	4,250–7,130
1998	1,970–3,870
1999	840–1,880

Table 57-6 Later UK and EC Action To Prevent BSE from Entering the Human Food Chain: A Simplified Account of Relevant Regulations (1995–1998)

Date	*Action*
15 December 1995	UK SBO Amendment Order essentially prohibited use of bovine vertebral column for products destined for human consumption, including mechanically recovered meat (MRM).
27 March 1996	EC ban on export from UK of live cattle, semen, or embryos; ban on bovine meat or products from cattle slaughtered in UK that could enter animal feed or human food chains; ban on bovine materials destined for use in medicinal products, cosmetics, or pharmaceutical products; and ban on mammalian-derived meat-and-bone meal (MBM).
29 March 1996	UK BSE Amendment Order prohibits sale or supply of any mammalian MBM or any feed containing it for feeding farm animals, horses, or farmed fish.
29 March 1996	Specified Bovine Material Order replaced UK SBO Order of 1995. Whole head of all cattle aged >6 months to be regarded as SBO (except tongue).
3 April 1996	UK 30-month Slaughter Scheme: All bovine animals >30 months at time of slaughter must not enter human food or animal feed chains.
4 April 1996	UK cattle identification regulations extended.
1 May 1996	Specified Bovine Materials (SBM) to be removed from carcasses and handled separately. UK Regulations on rendering and disposal brought into line with EU requirements.
1 May 1996	UK Regulations made more rigorous and applied to approved operators of incinerators or rendering plants and to licensed operators of licensed abattoirs.
10 June 1996	UK Feed Recall Scheme to collect and dispose of MBM or feed containing MBM still on site at farms, mills, or merchants' premises.
11 June 1996	EC ban on gelatin, tallow, and semen partially lifted.
1 July 1996	UK Cattle Passports Order requires mandatory cattle movement documents in GB for all cattle born from this date. (Computerized tracing planned to be on line by 1998.)
1 August 1996	UK Prohibition on possession of MBM where any livestock feed is kept; requirement for disposal and recall of MBM and cleansing and disinfection of places, vehicles, and equipment that might have been contaminated with MBM.
15 September 1996	UK ban on sale for human consumption of any part of the head of a sheep or goat (except the tongue).
16 December 1996	UK announces selective cull of cattle deemed most at risk of BSE.
24 December 1996	UK requires all UK plants producing gelatin from non-UK material to be registered.
16 December 1997	(UK) Deboning of all beef from all cattle aged >6 months at slaughter now required before sale to consumers.
22 December 1997	BSE Inquiry announced in UK.
1 January 1998	UK controls adopted on Specified Risk Material in line with EC recommendations.
15 April 1998	UK regulation: Cattle born after 1/1/98 must have a MAFF-approved eartag in each ear and a cattle passport.
29 July 1998	UK: Compulsory slaughter of scrapie-affected sheep and goats.

cannot be recorded until the full range of the incubation periods has run. Even then, we have to take account of possibly significant numbers of unrecognized but infected animals that are slaughtered or die for other reasons in the meanwhile. Further work is needed to determine, now, whether lateral transmission might account for some of the late cases and whether other factors are operating. If a further BSE mutant arose with an increased capacity for maternal or lateral spread among cattle, this might dramatically alter these forecasts, and additional controls would be necessary. Nevertheless, continuous study of the pathology of BSE and of the BSE agent's biological characteristics so far reveals that a single strain is responsible.

57.10 BSE IN MAN

57.10.1 What Is the Risk of Foodborne Transmission of BSE to Man?

It is not possible to give a direct answer, but it is helpful to consider the protective factors that may operate. All of the points reviewed above allow us to compile a list of reasons why man may be protected from the full effects of the BSE hazard. This analysis started with the opinions of the Southwood Committee[119] and was followed by others, including Taylor's careful assessments[133,134] and the views of Harrison and Roberts[65] and Will.[148] Many of the points were summarized in reviews of the evidence by Collee,[24–26] by Bradley and Wilesmith,[13] and Collee and Bradley.[27]

First, there was the concept of the species barrier with "interspecies variations in the prion gene so that differences between the encoded proteins may make prions (in the challenge) less able to modify the normal PrP of the host."[65] There are several variable components in the species barrier: variation in the *PrP* gene sequence of the donor and the recipient species, and the strain of the infecting agent.

Second, the oral route of challenge generally is regarded as very inefficient in this context; we have to look as far as the models of kuru and TME and BSE-like disease in one of the species of captive exotic ungulates to find evidence of apparently regular transmissibility by the oral route, and there are some doubts connected with each of these examples. In studies with orally delivered challenges fed to experimental animals, successful transmission was generally associated with very large doses.[9,58] Some captive wild Felidae that succumbed to nonexperimental oral infection may have consumed high-titer CNS tissues from cattle infected with the BSE agent. Other species were presumably similarly exposed and, so far, they seem to have been resistant. On the other hand, some captive bovids fed MBM supplement were highly susceptible. The outbreak of FSE possibly caused by transmission of the agent of BSE in pet food to domestic cats in Britain has provided an instructive model.

The third point is that many mouse bioassay experiments to determine the infectivity of tissues from cows with BSE indicate strongly that the BSE agent is not so widely distributed in detectable amounts in the tissues of the cow as the scrapie agent is distributed in sheep tissues.[82,83] High infectivity in sheep scrapie is associated with the brain and spinal cord, with medium infectivity in the spleen, tonsil, lymph nodes, distal ileum, and proximal colon. Infectivity also has been reported in the retina.[111] No detectable infectivity was recorded for skeletal muscle, milk, blood, and various other tissues. Similar studies with tissues from BSE-infected cows have, so far, indicated that infectivity is associated only with the brain and spinal cord; the assays were performed in mice by parenteral inoculation. The infectivity of the brain and the noninfectivity of some of the other tissues also was demonstrated by oral challenge experiments.[103,111,130] A very important point is that mice exposed to parenteral challenges with muscle, spleen, and placenta from BSE-infected cows did not show any evidence of a spongiform disease within their natural lifespan.

Until now, estimates of tissue infectivity in various experimental animal models have been based mainly on tests of infectivity in mice (mouse assay). With the subsequent realization that the mouse assay (ie, using intracerebral inoculations in a heterologous species to test bovine tissues) is perhaps 100–1000-fold less sensitive than an equivalent assay in the homologous species (ie, intracerebral tests of BSE-infected bovine preparations in calves), there has been a reconsideration of our views on the relative infectivity of various tissues in BSE. The mouse tests had indicated that the BSE agent is much less widely distributed in the tissues of infected cows than the scrapie agent in sheep. In naturally infected cattle, BSE infectivity as judged by mouse assay seemed to be restricted to the brain and other central nervous tissue and retina. Tests with high oral challenges in experimentally infected calves have since shown possible infectivity in distal ileum,[139] and, more recently, in bone marrow and dorsal root ganglia.

The widening concept of the potential infectivity of BSE-infected tissues from cases of the disease in

Next Page

animals and man has driven the authorities to introduce additional safety measures. These have included a ban on the sale for human consumption of beef on the bone and the exclusion of bovine bone marrow and dorsal root ganglia.

Of course, legislation and guidelines adopted in Britain and guidelines adopted in other countries already provided some possible protective cover.[111] For example, the various measures outlined elsewhere in this chapter to recognize and eliminate cases of BSE from the food chain and the imposition of the specified offals ban (with its further extension to apply also to calves less than 6 months old in regard to the intestine and thymus gland) should have further reduced the chances of the delivery of a significantly high oral challenge with the agent of BSE in our diet.

It is likely that man has been challenged orally with the scrapie agent in some sheep products for more than 2 centuries, but there is no recognized association between scrapie and human disease over that long period. The early evidence seemed to indicate that the BSE agent is a form of the scrapie agent that achieved a breakthrough in the cow. If we accepted this view, we would have to assume that a species barrier between the sheep and the cow, which had held for centuries, was broken by the "unnatural" circumstances that allowed overwhelming challenges to be delivered to herds of British cows in the period from the late 1970s until at least 1988. As we have discussed, the breaking of a species barrier and the adaptation of a pathogen to the new host has the potentially dangerous implication that other species barriers may be less secure; accordingly, we must proceed with caution—especially in the light of Diringer's theory.[48] Moreover, the back-transmission of the BSE agent from cows to sheep merits consideration,[27] and this is now under investigation, with some precautions already in place. Scrapie in sheep in the UK was only made notifiable in 1993, and compulsory slaughter of sheep (and goats) with scrapie was not introduced until 1998. Items presently banned for human consumption include the heads and spleens of all sheep. In the case of sheep more than 1 year old, vertebral columns are banned and meat recovered from vertebral columns is banned.

If BSE existed in cows (enzootically) before the present large-scale outbreak, there is little doubt that the factor precipitating the UK catastrophe was again the alteration of the rendering processes, and that the vehicles of the severe challenges were ruminant-derived protein supplements produced by these processes. It was thus necessary, in the late 1980s when BSE was recognized, to bring in severe measures to protect the public health in the UK against the theoretical hazard of ingesting high challenge doses of the BSE agent in bovine products.

Harrison and Roberts in 1992 regarded the BSE outbreak as "an accidental experiment on the dietary transmissibility of prion disease between sheep and cows."[65] These authors considered that a subsequent experiment on the transmission of BSE from cow to man probably occurred from 1986 to 1989, because BSE-contaminated products may have entered the human food chain at that time. They regarded the chance of BSE causing human disease as extremely small. We can add, again with hindsight, that the early recycling of affected cows in the process must have fueled the outbreak that either began with an ovine strain that became bovine-adapted, or else began with the boosting of a previously undetected (enzootic) bovine strain that was already bovine-adapted. Hence, the early 1980s saw the beginning of an extended "natural" experiment in cow-to-cow transmission of BSE (via rendering), and the mid-1980s saw the start of other natural experiments in direct transmission by possible vertical and lateral spread of BSE within affected herds.

Our experience in the transmission of prion diseases indicates that the oral route of challenge is much less effective than parenteral routes. Fortunately, the majority of the bovine-derived materials used for (parenteral) implantation or injection were produced from tissues or fluids that have been shown to contain no detectable BSE infectivity by bioassay in mice, but some preparations derived from bovine neural tissues have been used parenterally in the past[10] and some have been implanted intracerebrally in neurosurgical procedures. If, in future years, evidence links these with a BSE-like disease in man, it will be important to bear in mind that the risk associated with oral challenges is still likely to be much less by several orders of magnitude.[83,148] It will also be important to remember that our presently heightened awareness of the prion diseases will ensure that human encephalopathies and dementias will be reported and investigated more extensively in the next decade.[17,53,63,78] Until we have more specific markers for these diseases, we must guard against automatically assuming that, for want of a definitive diagnosis, the agent of BSE in Britain (and elsewhere in the world) is responsible for all human spongiform encephalopathies. Will, in 1991, considered it essential to minimize human exposure to the BSE agent in food and summarized the evidence for his view, at that time, that the consumption of beef (bovine muscle) is exceedingly unlikely to be hazardous.[148] The risk of foodborne transmission of BSE in the US was regarded by Moon as even lower than the low risk in the UK.[104] Cooking temperatures do not definitely inactivate the agents of scrapie or BSE, but they can reduce the titers of infectivity.[133,135] In the UK, and in any country in which BSE has been diagnosed in indigenous cows, it is reasonable to avoid eating bovine tissues in which high concentrations of the BSE agent are known to occur when a cow goes down with BSE (notably, brain and other specified offals that have been banned in the UK). There are justifiable worries about instances of carelessness, negligence, and fraud in British slaughterhouses and farms (*The [London] Times*, December 2, 1995) that may have frustrated our protective legislation in this context. When this chapter was completed in September 1998, the UK government had tightened regulations with further control measures (Table 57–6). After December 15, 1995, products destined for human consumption derived from bovine vertebral column, including mechanically recovered meat from this site, were banned. For operators outside abattoirs such as those in knackers' yards and hunt kennels, the whole backbone (apart from the tail) of a cow was to be removed and regarded as prohibited offal. This was because some abattoirs were leaving parts of the spinal cord attached to the carcass. Subsequently, the whole head (excluding the tongue) of cattle aged more than 6 months old was to be regarded as SBO. (The term SBO was replaced and extended by the term *specified bovine material* [SBM], on March 29, 1996.) Concern continues to be expressed about beefburgers and other processed meat products (pies, beef soups, stock cubes, and patés) in which the use of cattle brain and specified offal has been banned since 1989 to 1990, although brain from calves under 6 months of age still can be used. It may seem unreasonable that calf brains are still allowed into the food chain (*The [London] Observer,* Sunday, December 3, 1995). In a country with a continuing outbreak of BSE, some of us feel that it would be wise to ban the supply of bovine brains, spinal cord, and offal from cattle and calves of any age for human (or animal) consumption. The facts of the matter are, however, that data from a careful series of pathogenicity experiments with orally challenged calves showed no detectable infectivity in brains from these animals at least up to 22 months of age and 18 months after challenge. On April 3, 1996, the UK 30-month slaughter scheme ensured that all cattle over 30 months old at slaughter must not enter the human food or animal feed chains. As time goes on, cohorts of cattle aged up to 30 months are progressively more unlikely to have been exposed to infected feed, especially with the introduction of measures to recover MBM from sites indicated in Table 57–6 and to clean and disinfect these sites and equipment. The numbers of calves that may continue to be infected by maternal transmission also will decrease, and this may be accelerated by the selective cull introduced in December 1996. With the UK banning of bovine meat on the bone and bone marrow in December 1997, attention is again focused on products that are heavily dependent on bovine bones as source materials.

Gelatin. Gelatin extracted from bovine skin and bones is used widely in catering and confectionery and in the production of some pharmaceutical preparations, but is considered unlikely to be contaminated with the BSE agent,[101] although the US authorities presently are unconvinced. The Scientific Veterinary Committee (ScVC) in Brussels and others recommend that skulls and vertebrae should not be used as source materials for gelatin because there is a risk that infected brain or spinal cord could be present. Concentration of such infection could be important, even if the processing is rigorous. If tallow and gelatin destined for incorporation in human foods or medicines are derived from BSE-free cattle from closed BSE-free herds that had not been fed ruminant-derived protein, this would make assurance doubly sure. In February 1998, the EU Scientific Steering Committee (SSC) reported their discussions on gelatin and reached the following scientific opinions.

1. The preparation of gelatin and acceptable sources for human consumption or for cosmetics were defined. Two critical considerations are the traceability and treatment at the source of the raw materials, including the meticulous removal of specified risk materials. The SSC acknowledged the FDA (1997) opinion that gelatin can be produced safely from bovine hides from any country, provided that the hides have not been contaminated with specified risk materials and that hides from cattle with signs of neurological disease are excluded. The SSC considered that gelatin for human consumption could be prepared from bovine bones and skins without removal of specified risk materials if obtained from countries known to be BSE-free or "at negligible risk." In the case of sourcing from "lower risk countries," specified risk ma-

terials should first be removed and the origin should be certified to be exclusively from animals deemed fit for human consumption. For raw materials from "high-risk countries," and with exceptions restricted to special cases, only hides should be allowed and, even then, they must be from animals fit for human consumption. Materials sourced from countries of unknown status might be judged on their specific merits or might be considered as for those from high-risk countries.

2. Gelatin destined for pharmaceutical products and parenteral use was considered separately, and subclassified as (a) gelatin for oral or topical (excluding ophthalmic) use, and (b) gelatin for parenteral or ophthalmic administration or for use in implantable devices. For oral or topical use, the conditions set for food and cosmetic use should be met, but with special grade gelatin considered for topical products that might be applied to large areas of damaged skin or open wounds. Gelatin for parenteral, ophthalmic, or implantable use should be of special grade with appropriate purification procedures followed in its production. If gelatin is to be used as a reagent in the manufacture or production of pharmaceutical preparations, the more stringent controls should apply. Gelatin destined exclusively for industrial use in the production, for example, of photographic products and for various technical applications, should be prepared by an appropriate production process within the SSC guidelines; if ingestion of the gelatin or human exposure to it may be expected under normal conditions of use, the relevant conditions should apply. The original papers should be consulted for details of these careful and complex deliberations (see Institute of Food Science & Technology [IFST] [UK] at http://www.easynet.co.uk//ifst).

The emerging new evidence of BSE infectivity in the bone marrow and dorsal root ganglia of experimentally infected calves had repercussions, but the guidelines are presently held. Note that the recognized manufacturing process for gelatin includes at least four steps that each are known to reduce the titer of infectivity of spongiform encephalopathy agents. The initial degreasing step has an estimated reduction factor of about 100. Acid demineralization also has a factor of 100. Alkaline purification is even more powerfully inactivating with a factor of 1,000; and the sterilization process has a mean value of 100. As a result, the titer of infectivity of the raw material is said to be "probably reduced by a factor of the order of a thousand million (10^9)." There are areas of uncertainty in these calculations; for example, definitively sterilizing conditions for TSE agents in a proteinaceous mix would be likely to denature gelatin or at least alter some of its properties. Significantly, the UK gelatin manufacturers have decided to manufacture gelatin for edible or pharmaceutical use from raw materials derived entirely from non-UK sources.

Tallow. The SSC performed a similar risk assessment for tallow. An appropriate purification process was outlined with special reference to time, temperature, and pressure parameters and with conditions known to be effective in inactivating TSE agents achieved throughout the material being processed. Emphasis again was placed on the importance of the traceability of the raw material and its treatment at the origin, including the removal of specified risk materials. In the case of tallow destined for human or animal consumption or application, the source animals should be fit for human consumption. If the material is from countries with no BSE or classified as at negligible risk, processing can proceed permissively but with the precaution that the purification process should be appropriate and validated. If sourced from "lower risk" countries, the use of specified risk materials should be excluded and the processing should be validated. If the country of origin is deemed to be in the high-risk category, specified risk materials should be excluded, the purification process should be validated, and the product should be subjected to 133° C for 20 minutes at 3 bar pressure or an equivalent TSE-inactivating procedure. Source countries of unknown status should be assessed on their individual merits or regarded as high risk. A ban imposed by the European Commission on the export of tallow produced from cattle slaughtered in the UK was partially lifted in 1996. Regulations implementing the conditions came into force in the UK on March 15, 1997, and a further UK SBM order was made on March 28, 1997. This legislation required that all UK tallow for food, feed, pharmaceutical, medical, and cosmetic uses must be manufactured to export standards in registered plants and must be derived from raw materials free from SBM and specifically free from bovine vertebral column. The regulations also require manufacturers using UK-produced tallow in the production of food, animal feed, cosmetic, medical, or pharmaceutical products to use only tallow produced in a registered plant. European Community inspections of UK plants are to proceed now, with a view to allowing exports of UK tallow to be resumed.

Beef. With special reference to the consumption of British beef, there is now much evidence that the BSE agent is not present in detectable amount in the muscle (meat) of an infected cow, but dorsal root ganglia and bone marrow must be excluded. These recent findings accord with Aguzzi's concept of PrP expression in peripheral tissue as a requirement for pathogenesis[2,11] and oblige us to look again at the nerve content of the muscle of an infected animal. Note, in this context, that the limit of sensitivity of the intracerebral mouse bioassay on which our BSE detection methods presently depend is uncertain, but it is much more sensitive than any other practical method currently available and is perhaps 200,000 times more sensitive than the oral route.[83] The cow presumably would be the most sensitive bioassay species for BSE (and perhaps transgenic mice with bovine *PrP* genes). Inevitably, a cattle-based assay would take years, and the development of a practical transgenic mouse assay requires much work. Advanced bioassay work currently in cattle and mice at the Central Veterinary Laboratory, UK, (Ray Bradley, personal communication) confirms that tests in cows are much more sensitive than tests for BSE infectivity in mice. Note also, as detailed at several points elsewhere in this book, that other more definitely documented microbial hazards may be associated with the eating of inadequately cooked meat products or with contaminated processed foods.

Specified Risk Materials. The SSC of the EU listed specified risk materials and adopted the following opinion in January 1998 as a guide to categorizing the potential infectivity of the tissues of BSE-infected animals (essentially cattle, sheep, and goats). Organs associated with high infectivity or with a risk of significant contamination during slaughter (category 1) include brain, eyes, spinal cord, dorsal root ganglia, dura mater, pituitary, skull (entire head excluding tongue) and vertebral column, lungs, and ovine and caprine spleens. Organs in the medium-infectivity category 2 include the total intestine from duodenum to rectum, tonsils, bovine spleen, placenta, uterus and fetal tissue, cerebrospinal fluid, and lymph nodes. Organs with low potential infectivity (Category 3) include liver, pancreas, thymus, bone marrow, bones, nasal mucosa, and peripheral nerves. Category 4 (no detected infectivity) is large and includes skeletal muscle, milk, blood clot, and serum. This line of reasoning was extended by the SSC to develop a suggested list of specified risk materials to be excluded from human and animal consumption except when derived from a BSE-free country with what they regarded as a negligible risk of BSE. In effect, the specified risk materials included virtually all of those in their categories 1 and 2. Many of the items carried an exemption up to the age of 12 months (ie, those tissues from young calves, sheep, and goats were not excluded, but ovine and caprine spleens and bovine, ovine, and caprine intestine were to be excluded at all ages). In practice, the heads of sheep and goats at all ages may have to be removed. In countries at high risk of BSE, it was considered probably appropriate to reduce the age limit for all of the specified risk materials from 12 to 6 months. And all tissues from cattle over 30 months of age might be considered as specified risk materials. The SSC opinion was that long bones from cattle under 30 months of age with no clinical signs of BSE may be considered as acceptable for human consumption.

57.10.2 Human Susceptibility to the BSE Agent

By mid-1998, when this chapter was finalized, 26 cases of nvCJD in the UK and 1 in France had been recognized and confirmed. All of the nvCJD cases examined to date are homozygous for methionine at codon 129 of the *PrP* gene (MM). The aminoacid 129 position is generally not polymorphic in animals; with few exceptions, animals are uniformly homozygous for methionine. In the general human population, MM homozygosity occurs in about 37%, valine homozygosity (VV) in 11%, and heterozygosity (MV) in about 51%. MM homozygosity is therefore thought to be a susceptibility factor for nvCJD; however, Zeidler and colleagues caution that this does not necessarily indicate that MV or VV individuals will be entirely resistant to nvCJD. It is possible, for example, that patients with these alternative genotypes might develop disease after a longer incubation period and perhaps with a different clinical presentation.[163] Incidentally, the MM genotype predominates (but not absolutely) among patients with sporadic and some forms of acquired CJD.

57.10.3 The Theoretical Pathogenesis of BSE in Man

It is likely that the patients who have so far developed nvCJD were severely challenged with the infective agent, possibly in their teenage years, or that some predisposing factor or factors operated in each case—but we remain uncertain. The families concerned have our greatest sympathy; they require much support, and the situation merits our constant concern. The likeliest time for such challenges to be delivered to man was when BSE-infected bovine products had free access to the human food chain (ie, in the mid-1980s and into the 1990s before the early control measures were effectively enforced). Perhaps the likely incubation period may be 5 to 10 years or more. Thus, a 14-year-old consuming an infective dose in 1986 might show early signs of nvCJD in the mid-1990s and would die 1 to 3 years later. The death of a young girl who had been a vegetarian for 11 years raises the possibility that some apparently nonanimal foodstuff or preparation may have contained a bovine ingredient or that the possible incubation period has to be measured in decades; moreover, the period of possible exposure to foodborne challenges with the BSE agent in the UK may extend back to the early 1980s or the 1970s.

Blood and Blood Products. In 1996, Dr Dealler[40] carefully reviewed his assessments of the risk of BSE transmission to humans from food, and he considered that human blood transfusion from a donor who had eaten BSE-infected food and was incubating the disease could be a hazard during the subclinical phase when the agent may be present in the blood (see commentary by Janet Morgan[106]). This speculation arises from evidence of transmission of other TSEs by blood and from the recent evidence of maternal transmission of BSE from cow to calf; and it presupposes bloodborne spread in that instance. Operskalski and Mosley pointed out in 1995[108] that hemophiliacs across the world have received large amounts of fresh blood, fresh-frozen plasma, and fibrinogen, and many have had "huge amounts" of clotting factor concentrates. There has been more than enough time for CJD to be seen in hemophiliacs if it is transmissible in this way, yet in three to four decades there has been not a single case of CJD recognized in a hemophiliac. In this context, we should be careful to discriminate between essentially cell-free blood products and whole blood that will contain white blood cells (leucocytes) as well as red blood cells. It is possible that the prions are carried in leucocytes; however, cell-free blood products not prepared from leuco-depleted blood will contain the contents of the cells. In 1994, CJD was diagnosed in a long-time plasma donor in the US, and this led to plasma quarantine and other actions being taken in the US. I am not aware of any scientifically documented evidence that CJD ever has been transmitted to man by human blood, but CJD has been transmitted experimentally to animals from human blood.[96]

Collections of abnormal prion protein (PrP^{res}) have been detected in tonsil tissue of human patients with nvCJD[69] and in the appendix of a patient who later developed nvCJD.[138] If the detection of PrP^{res} by microscopy of immunostained tissue can be equated with potential infectivity, this raises paradoxically conflicting reactions:

1. There is the worrying possibility that the agent of nvCJD has a much wider potential for tissue infectivity in man than our earlier mouse tests with the BSE agent led us to anticipate. If nvCJD patients show accumulations of PrP^{res} in lymphoid tissues, we cannot rule out possible bloodborne transmission of nvCJD, perhaps within leucocytes in the blood, at some stage in the development of the disease. Dr Dealler's warning is endorsed. Increasing anxiety regarding the possible infectivity of bloodborne cells and other tissues in human cases of nvCJD and the present nonavailability of a test to determine preclinical cases have led to restrictions on UK-derived human blood products, lest blood donors incubating undetected nvCJD (or sporadic CJD, for that matter, though sporadic CJD is not known to have such a wide tissue distribution) might have contaminated a preparation or a batch of material destined for human use.[77] The British government began to take action on blood products in this context in 1996[106] and in 1997 to 1998.
2. There is the hope that tests on human tonsil, appendix, and other lymphoid tissues may shed light on the pathogenesis of nvCJD in man. This could be linked with the ultimate goal of developing a blood-based test for the early diagnosis of CJD and nvCJD in man. It is to be hoped that parallel research on nonhuman primates may provide valuable clues.

The Oral Route. Let us concentrate now more specifically on the possibility of the oral route of transmission (a possible foodborne hazard) from cow to man, though surgically implanted or injected materials of bovine origin also could be candidate vehicles of infection with BSE.[142] About 1 gram of highly infective cattle brain is considered to be sufficient to produce BSE in a cow by the oral route. The ingestion of a quantity of infected bovine brain or a product containing this could have delivered a challenge of prions into the human alimentary tract before our control measures were enforced. The heat-resistance of the prions would protect against cooking temperatures, although there could be substantial reduction of infectivity.[135,136] The proteinase resistance of prions might protect against proteolytic digestion in the gut (not yet formally proved).

The prions might be taken up by the lymphoreticular system via M cells in Peyer's patches throughout the gut. (It is even possible that they could be taken up by lymphoid tissues in the oropharynx.) Perhaps host clearance mechanisms might be crucially compromised on occasion by another infecting agent such as that of infectious mononucleosis, or measles, or influenza. The prions then might transform normal host PrP to boost their numbers in the local cells and to build up the infection in organs such as the spleen and other lymphoreticular tissues. Hill and colleagues have shown how abnormal PrP accumulates in the lymphoid tissue of the tonsil in nvCJD,[69] and we now know that the appendix may be involved. Kimberlin and Walker's studies of the dynamics of replication of the sheep scrapie agent indicate that agent replication within the nervous system and not the lymphoreticular system is a key factor,[84] and Blättler and colleagues have shown, in studies of scrapie in mice, that a continuous chain of PrP-expressing tissue is needed for the prions to spread from peripheral sites to the CNS.[11] Colonization of the lymphatic system is probably necessary for neuroinvasion, but further PrP^{res} expression, possibly in the peripheral nervous system, seems to be necessary for successful CNS involvement. PrP is particularly abundant in neurones, and Aguzzi postulates a "neuro-immune connection" in the spread of prions in the body.[2] We can theorize by analogy with the neurotropism of poliomyelitis from the gut, or of rabies virus, or tetanus toxin from a wound. By tracking along local splanchnic (intestinal) nerves or other peripheral nerves to the spinal cord, the prions would then gain access to the brain where, apparently, the production of abnormal PrP is up-regulated and neurological function is impaired progressively.

57.10.4 Surveillance Work: Past, Present, and Future

The epidemiology of CJD and nvCJD in the UK is being monitored carefully by Dr R.G. Will and his team at Edinburgh.[118] Important studies that have sought to identify risk factors for sporadic CJD in the past include those of Bobowick et al. in 1973,[12] Masters et al. in 1979,[99] Kondo and Kuroiwa in 1982,[89] Will et al. in 1986,[151] Davanipour et al. in 1985 and 1987,[35,36] Brown et al. in 1987,[15] and Harries-Jones et al. in 1988.[64] And we add much recent speculation, summarized in this chapter, on possible risk factors for nvCJD.

What must now be done? Further careful clinical, pathological, epidemiological, and microbiological studies of sporadic and other CJD cases (for example, studies by Brown and colleagues[15,16]) will give answers if the present level of international cooperation and liaison is sustained into the forthcoming century. The continuation of the UK surveillance program is vital and it must be ensured for several decades while it adapts to changing circumstances.[149,151,152] The discovery that the agents of nvCJD and BSE are identical is accepted as proof that the agent of BSE has been transmitted to man. The annual numbers of deaths from various forms of CJD recorded in Britain are given in Table 57–7. In 1990, when accurate data began to be available and hospital referral of any suspected case was recorded, there were 33 cases. The numbers increased thereafter, perhaps partly due to improved surveillance and awareness; from 1991 to 1998, annual totals of 36, 51, 46, 59, 47, 60, 79, and 72 until the end of 1998 are a cause for some anxiety, and the contribution of nvCJD cases (13 in 1995–1996, 10 in 1997, and 16 in 1998) clearly fuels our anxiety. There is an inevitable delay in getting true figures for the current year because investigations are still in progress. Several workers believe that there is still under-reporting because of missed or misdiagnosed cases of sporadic CJD.[149] New diagnostic tests for CJD are needed urgently.[88] The production of a cerebrospinal fluid test for human and animal transmissible spongiform encephalopathies is a promising step forward,[75,93,153,164] and the preparation of monoclonal antibodies specific for PrP^{res}[87,105] is most encouraging, while we anxiously await further developments with the new variant disease.

Of course, continuing surveillance of BSE and scrapie in cattle and sheep in the UK is essential, and this must be actively extended worldwide. There are worrying suggestions in the news media and elsewhere that possible cases of BSE in cattle are being missed in Europe and the US, that information may be suppressed in some countries, or that mismanagement of feedstuffs abroad may have disastrous consequences.[14,117] The need for increased vigilance and rigor surely must be obvious. An official Inquiry was set up in London under the chairmanship of Lord

Table 57–7 Annual Numbers of Deaths from CJD in the UK (1985–1998)

		Deaths of Definite and Probable Cases of CJD in UK					
Year	*Referrals*	*Sporadic*	*Iatrogenic*	*Familial*	*GSS*	*nvCJD*	*Total*
1985	—	26	1	1	0	—	28
1986	—	26	0	0	0	—	26
1987	—	23	0	0	1	—	24

1997	161	58	6	4	1	10	79
1998	150	50	3	3	0	16	72

Total number of definite and probable cases of nvCJD to end of 1998 = 39 UK patients.

Source: from Department of Health Press Release, August 3, 1998, and CJD Surveillance Unit, UK.

Justice Phillips in 1998 and a report of its very detailed deliberations is anticipated in mid-2000.

57.11 CONCLUDING REMARKS

On present evidence, there is understandable concern that many of the UK population will have eaten processed meat products incorporating potentially BSE-infected bovine tissues—such as brain and other offals banned since 1989—at some time in the 1980s, while doubt remained about the rigor of our enforcement procedures in the UK even up to 1995. Calf brain was not banned when this chapter was finalized in late 1998; there is no persuasive scientific evidence that its consumption is hazardous, but the sensitivity of mouse bioassays used to detect BSE infectivity is not absolute. Inadvertent parenteral experiments on the possible transmissibility of BSE to man that might have taken place in the 1980s must include the injection or implantation of bovine-derived materials that were in common medical and surgical use in Britain and across the world in the 1970s and 1980s,[10,142,148] but we have no evidence to incriminate injections or implantations of bovine-derived materials or of substances associated with bovine products in pharmaceutical or cosmetic preparations.

The recognition of 39 British cases of nvCJD, plus one in France, is most worrying. Studies reported in October 1997 show that nvCJD is distinct from other forms of CJD and they provide convincing evidence that the agents of nvCJD and BSE are the same. Moreover, the agents recovered from cats with FSE in Britain and from captive exotic bovids that went down with BSE in British zoos had the same profile as agents recovered from cattle with BSE.

Diringer's belief in the wider infective potential of the BSE agent is sustained, but the debated link with scrapie remains to be resolved. Note, however, that the CJD illnesses in our farmers that gave rise to much recent speculation did not have the characteristic clinical features of nvCJD, and the agent recovered from such cases does not have the profile of the BSE agent. Is it possible that sporadic CJD has some other relationship with animal prion diseases that we do not yet recognize, or might it be that the BSE agent is only one of several prion agents that might pass directly or indirectly from animals to man? We do not know.

There is much in biomedical science that is uncertain. The transmissible encephalopathies reveal the facts slowly while some impatient observers press for draconian measures and criticize the steps that have been taken by a responsible and well-informed administration in Britain, advised by scientists of world class who have to work with great care for the safety of themselves and others.[1] Several scientists, frustrated by apparent bureaucratic inertia, have joined the opposition,[41–43,80,91] and we should have paid more attention to some of their views, but many of the critics have not acknowledged the complexity of the problems and the caliber of the scientists and administrators involved. It is a blessing that the pioneer work on scrapie was done in Britain by Gordon[60] and Greig[62] and Wilson and Stamp and others,[131,157] and that continuity was ensured by the work of scientists such as Dickinson, Fraser, Hadlow, and Kimberlin[46,47,84] and by Hope and the neuropathogenesis group at Edinburgh.[76] Meanwhile, the splendid investigations undertaken in the US and elsewhere by Gajdusek and his teams[12,15,17,56,58,59] gave us insight into the human model of kuru and beyond, and the brilliant persistence of Prusiner and his colleagues in developing the concept of prions[112–115] complemented our growing awareness of new mechanisms of disease. Prion theory continues to be challenged (see Manuelidis,[97] Alper,[6] Finkel,[54] and McCarthy[95]), but it has come a long way. At the same time, investigators recruited by, or collaborating with, Matthews,[33] Collinge,[29,30] Brown,[15–18] and Will[18,150–153] and others kept us in touch with the expanding story of CJD in man. The remarkable work done by Wilesmith and Bradley and their groups[13,144–147] after the discovery of BSE in cows by Wells and his coworkers[140] ensured that the UK authorities have continued to have all of the facts on BSE as promptly and as accurately as possible, despite the complexity of investigations in this field. And we owe a debt to the Southwood team for their prompt and accurate conclusions based on the evidence available at the time.[119] The continuing care of workers such as Kimberlin,[83] Tyrrell,[130] Taylor,[133–136] Fraser,[55] Bruce,[19,20] Almond,[4] Pattison,[5,109] and many others is admirable. It is essential that the necessary resources should be provided to ensure that the vital surveillance of BSE and CJD and scrapie and the associated research and advisory services are sustained over the next two decades. It is also imperative that present control measures and any further precautionary orders be rigorously enforced in the UK and abroad.

The author of a chapter in a scientific textbook cannot expect to be absolutely up-to-date even in the year of publication. The facts of BSE as we presently understand them allow us to hope in the late 1990s that the worst of the bovine outbreak is over, as far as British cattle stocks are concerned. There are some worries about the control of BSE abroad and possibly in UK sheep.[27] The outlook for man is uncertain. The avenue of infection was almost certainly the oral route. It is most unlikely that cow's milk could be the vehicle, and there is no evidence that (unprocessed) prime beef could have transmitted BSE to man. The supplementary precautions introduced in the mid-1990s add to this assurance. The likely vehicles of infection for man were various bovine products associated with significant BSE infectivity—infected bovine brain and other offals before they were banned in 1989 and before the ban was rigorously imposed and made fully effective in the mid-1990s when other loopholes were closed; for example, mechanically recovered meat from sites such as the vertebral column was relatively recently regarded and controlled as another probable vehicle. We cannot yet entirely exclude other species or vehicles from possible involvement. The number of human patients known to be affected with nvCJD by March 1, 1999 is 40 in the UK plus 1 case in France. Sadly, we must anticipate more human cases. In early 1997, senior and well-informed biomedical scientists made tentative predictions based on various assumptions. On this occasion, they were reported responsibly. If the numbers of patients affected remain low at less than 20 per year for the next few years, the total number of human cases may be 100 or fewer. But if there is an annual doubling or tripling of new cases in the years after 1996, there could be hundreds or thousands of cases. And a worse-case scenario of tens of thousands of cases was envisaged if extended incubation periods of 20 or 30 years occurred. By early 1999, we have seen 40 cases in a population of about 55 million and we think that the incubation periods have been of the order of 5 to 12 years. We must expect to see more evidence of the agent's potential to cause human disease within the next decade at least. There are substantial grounds for the belief that BSE is not readily transmissible to man, but we must wait a decade or two with "substantial uncertainty" into the forthcoming century for the information that might endorse or challenge this optimism.

58.1 INTRODUCTION

The production, distribution, and marketing of foods with good microbiological quality and safety require control to be exercised over three different categories of microorganisms: Those that have the potential to cause foodborne diseases, those that cause food spoilage, and those that grow and produce desirable changes. Although extensive control procedures are needed to manufacture fermented products, such procedures will not be addressed in this chapter, which will instead focus on the control of pathogens and spoilage microorganisms; for information on fermented products, see Chapters 19, 23, and 26.

Like much of microbiology, the general strategy for the control of pathogens and spoilage microorganisms goes back to Louis Pasteur and his work in the 1860s. This strategy is basically one of exclusion, which requires reducing or eliminating the initial microbial load, preventing or minimizing further contamination (or recontamination), and, where necessary and feasible, preventing or delaying their subsequent growth in a food. The responsibility for developing and implementing this strategy belongs to all those involved in the food chain (ie, plough to plate); each has to focus on the ways of most effectively and efficiently ensuring that the procedures they apply will lead to the production of a safe and wholesome product.

For many years food producers, processors, retailers, and regulators relied on the use of Good Manufacturing Practice (GMP), control of hygiene, and microbiological testing of end-products to produce foods that are microbiologically safe and stable. As concern about the microbiological safety and quality of foods has increased, the shortcomings of this traditional approach have become recognized.[24,30,50,65] In recent years, therefore, this approach has been strengthened by the use of the Hazard Analysis Critical Control Point (HACCP) system and application of the concepts of quality assurance and quality management.

The aim of this chapter is to outline the way in which GMP, HACCP, and quality systems can be used in an integrated and effective way to ensure the production of microbiologically safe and stable foods.

The author wishes to thank Tony Baird-Parker and Tony Mayes for their useful suggestions and assistance in developing this chapter.

58.2 AN INTEGRATED APPROACH TO CONTROL MICROBIOLOGICAL QUALITY AND SAFETY

Food should be safe with respect to microorganisms capable of causing foodborne diseases and remain wholesome to the end of its shelf life. Absolute product safety (ie, freedom from all microbiological risks) is not achievable. The problem that regulatory authorities and food companies must face is to reduce such risks to acceptable and predictable levels, taking into account the cost-benefit implications involved in their control.

Two procedures can be used in tandem to identify the microbiological risks of concern in foodstuffs and what specific measures need to be applied for their control. The first, which is principally the function of the regulatory authorities, consists of applying a formal risk assessment procedure to determine whether a microbiological hazard, or a group of hazards, is of significant concern in foods consumed by a designated population and what measures should be generally applied for its control.[63] The methodology and use of risk assessment for this purpose are discussed in detail in Chapter 65. The second, which will be discussed in this chapter, will ideally follow from the recommendations of the first procedure, and is the development and application by the food industry of specific procedures to control microbiological hazards at their source, recognizing that it is the responsibility of industry to ensure—as far as is reasonably possible—that products offered for sale are safe.

The management of a food company is responsible for establishing a product safety policy, for defining the objectives to meet this policy, and for implementing these through appropriate programs. In addition to establishing means for adequate control and assurance of the safety of their products, management should provide means for assessing the performance of programs to ensure safety and to identify means for increasing their effectiveness and efficiency.

Design is crucial, and safety should be adopted as a basic design parameter. Designing for microbiological safety encompasses not only the product, but also the process and its components, such as the factory, equipment, people, and any specific treatment used to eliminate or minimize significant microbiological concerns. Manufacturing is a key function. At all stages, from procurement of raw materials and ingredients to final product dispatch, care must be taken to control all factors and activities that affect product safety. Distribution and sale also play a significant part through appropriate labelling (such as storage and use information to distributors and consumers). Observation of consumer practices and investigation of complaints also provide data to improve product and process design.

Setting apart managerial practices, which are far beyond the scope of this chapter, implementing control at the source to manufacture safe and wholesome food requires appropriate tools to be used in an integrated manner (Figure 58–1). This figure shows how GMP, HACCP, and quality management systems can be used to build a structured approach to the production of safe and high-quality foods.

GMP documents, and specifically the hygiene requirements they contain, describe and define the basic conditions for the hygienic production of a foodstuff. These usually will include requirements for: the hygienic design, construction, and operation of the manufacturing plant; the hygienic construction and use of food processing equipment; scheduled maintenance and cleaning of equipment and facilities; and personnel training and their hygiene requirements. Details of these requirements will be found in Chapter 59 and Section 58.3.

HACCP principles have gained worldwide acceptance as the most effective means of ensuring that foods are safe to eat.[16] The HACCP system is a structured approach to hazard management that aims to prevent product safety problems by identifying those hazards (biological, chemical, or physical agents) associated with the production, distribution, and sale of a particular foodstuff and means for their control to safe levels. Use of HACCP results in a safety assurance plan and system specific to a given product, its process of production, and the hazards involved. It can only be applied to a production operation applying GMP and cannot replace the need to apply GMP requirements. A detailed discussion and description of the use of HACCP will be found in Section 58.4.

A company producing a foodstuff must organize itself in such a way that all factors that affect product features and characteristics, including technical, administrative, and human factors, are under control. Such control should be aimed at the prevention of problems and toward their elimination or reduction. Such an organizational approach is broader in scope than product safety, and encompasses all quality attributes. The companywide quality approach is developed appropriately and implemented through a quality system that covers the organizational structure, responsibilities, procedures, processes, and re-

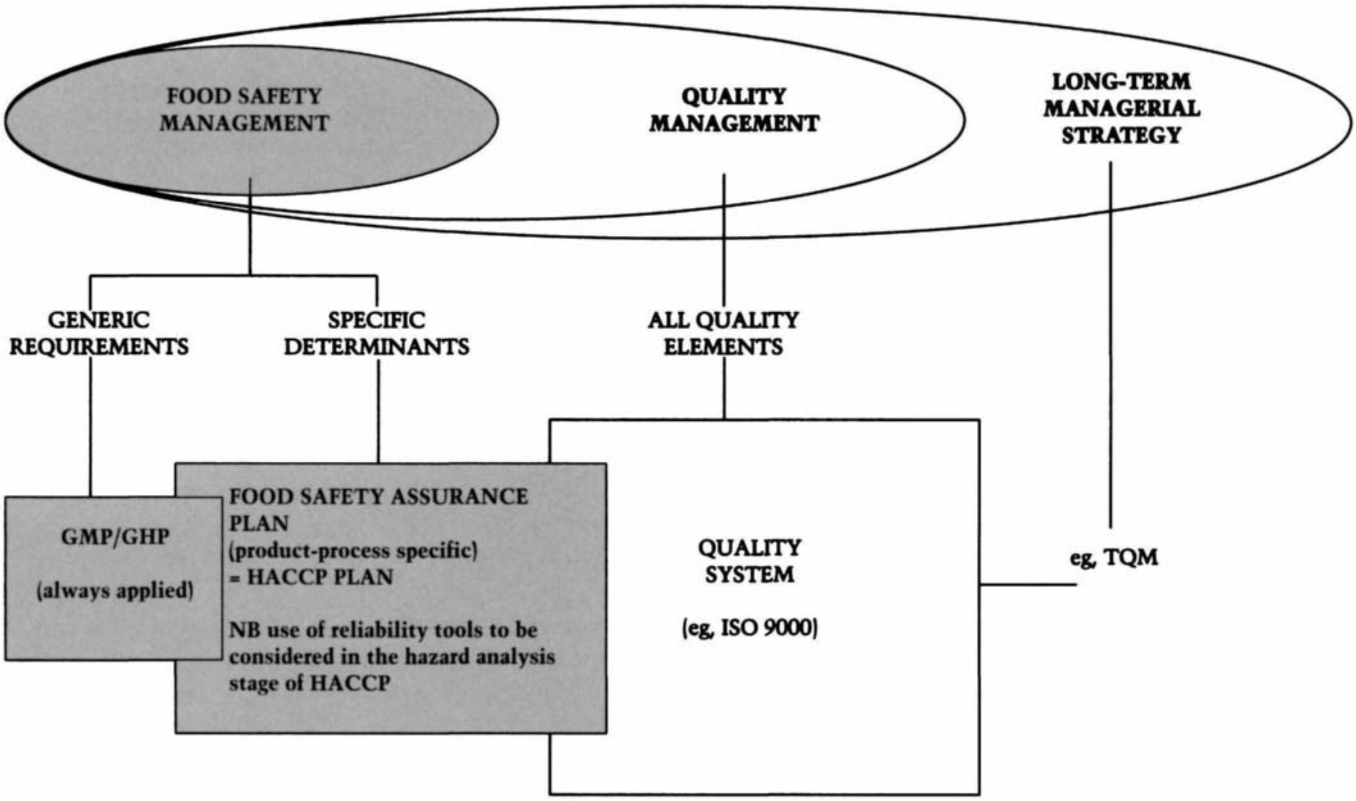

Figure 58–1 An Integrated Approach To Control the Microbiological Safety and Quality of Foods. *Source:* Reprinted with permission from ILSI Europe, *Food Safety Management Tools*, © 1998, International Life Science Institute.

sources needed to implement the overall management of quality. A quality system applies to, and interacts with, all phases of a product cycle, from marketing and design, through procurement and production, to distribution and sale. Specific guidance tools have been designed to aid food manufacturers in establishing such quality systems, among which the ISO 9000 series of Quality Management and Quality Assurance Standards have achieved worldwide recognition and acceptance.[33–37]

Within the framework of a quality system, the specific practices related to a given product and attribute (eg, safety) are specifically addressed in a specific plan (eg, a product safety assurance plan). Such a specific safety assurance plan is an intimate part of the quality system but can be used separately, in contractual or regulatory situations, to provide evidence of adherence to specific expectations or requirements (see Section 58.5 for details).

Finally, for achieving a permanent improvement in company performance, including safety as a key parameter, a more cultural and less hierarchical approach to management, based on the participation of all members of an organization, is to be recommended. This is the Total Quality Management (TQM) approach, which complements the approaches previously mentioned. It is important for the long-term success of a business, giving, through greater commitment and motivation of the total work force, better customer satisfaction. Further information on TQM can be found in the literature.[16,18,39,49,56]

While ideally every operator would benefit from the combined strengths of applying GMP, HACCP, and a quality system, practical implementation needs to be flexible and to be only as comprehensive as necessary. Two factors should govern these: the level of safety assurance required, which directs the certainty of controls needed, and the complexity of products produced and the production process.

GMP, particularly basic hygiene requirements, should be applied always. For low-risk products manufactured or processed using traditional procedures, the application of GMP usually will provide adequate security; an HACCP plan is not likely to be necessary or needs only to be of limited extent, un-

less required by law. However, for microbiologically sensitive products such as low-acid canned foods, chill-stored cooked meats, or complex operations involving a number of stages, and where risks of microbiological contamination are high, a detailed safety assurance plan based on HACCP is necessary to focus on those requirements critical for product safety.

Where the complexity of an organization increases with several levels of responsibilities among staff and where a number of departments contribute to the production of a food, a top-down structured approach to ensuring that safety requirements are met is necessary. Thus such a company should have a quality system in place to provide evidence that it is properly organized to control all stages and activities that affect product quality and safety.

58.3 APPLICATION OF GOOD MANUFACTURING PRACTICE

58.3.1 General Concepts

GMP defines and documents all requirements (premises, equipment, and operating practices) necessary for the production of food of acceptable quality.[28] With respect to the microbiological safety and quality requirements of such a food, it specifies the basic hygiene measures that all establishments covered by the scope of a GMP should meet. As was mentioned previously, these basic hygiene measures are a prerequisite to the application of HACCP, allowing HACCP to focus on steps, practices, or procedures critical for the safe processing or handling of a food in a particular establishment (see Section 58.4).

GMP documents in the form of regulations have been developed by regulatory authorities (eg, the US regulations on GMP),[10] the format of which is shown in Exhibit 58–1.

Other documents have been developed in the form of codes of hygienic practice by international organizations such as the Food Hygiene Committee of the Food and Agriculture Organization/World Health Organization (WHO) Codex Alimentarius Commission.[11] In addition, a large number of good manufacturing and hygiene codes have been issued by the food manufacturing and processing industries, often in cooperation with other groups and regulatory bodies, and on a national or international basis.[27] Such codes, although usually advisory, provide a reference point for both the guidance of manufacturers and enforcement authorities. Some are specific codes containing requirements for production of a specific foodstuff, whereas some are general codes covering the principles common to the production of the majority of foods. The latter may be complemented by specific codes for the production of specific types of foods. Thus the European Union Directive on the Hygiene of Foodstuffs (93/43/EEC) mandates basic hygiene requirements for food production, distribution, and sale but leaves industry to document any additional and specific hygiene requirements in the form of nonmandatory guides.

Generally, GMP documents address the following activities: the hygienic design and construction of food production premises; the hygienic design, construction, and use of food processing equipment; cleaning and disinfection of food premises and equipment; selection of raw materials and production conditions; training and hygiene of personnel; and appropriate documentation.[11,55] These activities are discussed in the following paragraphs and considered in more detail, together with specific examples of their application, in Chapter 59.

58.3.2 Hygienic Design and Construction of Food Manufacturing Premises

Appropriate design and construction of premises are necessary to limit entry, multiplication, and spread of microorganisms in the environment where a food is being produced or manufactured and, most importantly, to prevent or minimize cross-contamination of the products. Important aspects to be considered include the following:

Control of Conditions External to the Facility. To minimize the entry of contaminants into the plant, surfaces used for foot and vehicle traffic should be paved; covered containers should be used for rubbish; weeds and rubbish should be regularly removed; and unwanted equipment stored away from production areas.

Rooms Should Be Arranged To Ensure Straight-Through Flow of Products from Raw Materials to Final Product. Areas where potentially contaminated raw materials or other materials are handled should be adequately separated from areas where final product is handled. In "high-risk" areas, where prevention of cross-contamination is crucial, segregation also should be extended to staff working in them and any fixed or mobile equipment used.

Durability, Integrity, and Cleanability of Surfaces of Structural Components of Buildings and Facilities (Floors, Walls, and Ceilings). Materials used should be durable, impervious, nonporous, easy-to-clean (particular attention should be paid to avoid parts that are difficult to clean such as corners at junction between floor and walls) and free from cracks and crevices. Occupational safety considerations must not be overlooked (eg, nonslip floors). All surfaces must be well maintained and readily cleaned.

Control of the Environment. Air flow should be directed from clean to dirty products to minimize the spread of microbial contaminants by air. Filters, ducts, and other plant use of air conditioning should be inspected frequently, cleaned, and maintained properly. Temperature should be controlled to avoid major variations in room temperature because large differences of temperature between air and product may result in condensation and a source of microbial contamination.

Water Supply and Drainage Systems. Water used in processing should be both potable and of good microbiological quality. An ample and suitably located supply should be provided at the temperature necessary for use. To prevent contamination, cross-connection of plumbing with nonpotable water supply should be eliminated and back-flow prevention devices installed wherever back-flow or back-siphonage may occur. Special care should be taken in the design of effluent disposal systems that should be constructed and serviced so that the flow is always directed away from the production areas, with no possibility of back-flow or seepage.

Pest Control. Rodents, insects, birds, or other animals can be carriers of spoilage or pathogenic microorganisms. Measures for pest control include:

- elimination of breeding places and natural habitats in the surroundings of the plant such as weeds, brush, tall grass, litter, waste or refuse, and stagnant water
- actively excluding or restricting access to food storage and processing areas by using screens on windows, air curtains, or automatic closing devices on doors and sealing cracks, crevices, and holes
- and setting up extermination procedures (elimination of nesting sites, installing electrocution devices for insects, and the use of chemicals or biological treatments).[58] The outside of the facility should be inspected regularly for new places where pests could enter.

Appropriate Design, Location, and Maintenance of Sanitary Facilities To Minimize Potential Sources of Contamination. These include water supply and distribution systems, handwashing facilities, clothes changing areas, sewage disposal, and the storage and removal of waste.

58.3.3 Hygienic Design and Construction of Food Processing Equipment

When selecting food processing equipment, consideration is often given only to requirements such as suitability to perform the intended function, size needed for the production rate, reliability, ease of operation and technical maintenance, compatibility with other equipment, safety of operators, and cost. Too often, little consideration is given to hygienic design aspects of equipment; poor design and construction can lead to microbiological contamination of products. The main identified factor causing unsatisfactory microbiological performance is poor cleanability that may result from unsuitable construction materials; poor design of specific parts such as injectors, gaskets, glands, valves, or pumps; inadequate rounded corners, rolled edges, sharp angles, and poor welds; and existence of void spaces and dead legs inaccessible to cleaning fluids (eg, in clean-in-place [CIP] systems). Information on the correct design of such processing equipment and components will be found in Chapter 59.

Other conditions allowing microbial build-up and product contamination may result from the inability to drain equipment properly, poor accessibility to the equipment itself or to specific parts or surfaces in direct contact with food, poor repair, maintenance, and improper use of equipment.

58.3.4 Cleaning and Disinfection of Food Premises and Equipment

A regular cleaning and disinfection program is crucial to plant and food hygiene. Such a program should be treated as an integral part of the production process and "not regarded as an end-of-shift chore, liable to be hurried or superficial";[1] it should include both product contact surfaces and associated areas such as walls, floors, and ceilings.

Sanitary operations in food processing have two purposes. The first is cleaning to remove food residues that provide the nutrients necessary for microbial growth and may prevent proper functioning of equipment. It also removes the majority of microbes through the physical action of washing and rinsing. The second is disinfection (or sanitization) intended to reduce the microbial population that adhere and survive cleaning to a level where they will not be a significant source of microbial contamination of product coming into contact with the equipment. After cleaning and disinfection, the areas must be protected from recontamination before use.

Wet cleaning involves:

1. Selection of a suitable system (high pressure low volume; low pressure high volume; CIP systems, manual, foam/gel) depending on the design of the equipment or area to be cleaned, the soil type (tenacious or water soluble), the soil level, the design features, materials of construction, and operational characteristics of the equipment and conditions within the facility.
2. Selection of chemicals (detergents and disinfectants) taking into account properties such as the spectrum of antimicrobial activity (Gram-positive bacteria, Gram-negative bacteria, spores, bacteriophages), corrosiveness, irritability to skin, performance in hard water, presence of organic matter, incompatibility with equipment or other cleaning and disinfecting agents, stability of use solution, stability of hot solution, effectiveness at use pH, whether leaving active residues, maximum level permitted by law, and cost.[13,14]
3. Determination of an appropriate cleaning procedure or cycle including brushing, scraping, prerinsing, immersion in detergent, rinsing, disinfection, drying step, or a combination of these. The specific aims of these procedures are to control four basic factors (ie, mechanical force, concentration of chemicals used, temperature, and contact time). It should be kept in mind that with the exception of specific products, such as combined detergent-disinfectant products (detergent sanitizers), most disinfectants are ineffective in the presence of food residues.

Dry cleaning of a plant used for the processing of dry foods or ingredients presents special problems because the equipment is not usually designed for wet cleaning; moisture allows dry foods to support microbial growth and/or result in the formation of difficult-to-remove deposits. In dry processes, cleaning usually involves mechanical action (scraping or brushing), use of vacuum cleaners, and, where necessary, disinfection with ethanol (70%), which vaporizes quickly and leaves the surface of the equipment dry. The possible use of carbon dioxide freezing and acoustic devices is under consideration for dry cleaning but is generally too costly for general use.

Detailed technical information on cleaning equipment, chemical agents, and their use can be found in a number of publications.[19,21,24,29,43,57] (See also Chapter 59.)

In the framework of GMPs, the management of any food establishment is responsible for maintaining an appropriate cleaning and disinfection program. The following aspects should be considered:[22]

Selection of Type of Cleaning Staff. This may include: hiring the services of staff from a specialized company; using its own cleaning staff; cleaning by production personnel; or a combination of these such as production personnel beginning the cleaning process before leaving the work area and handing over to separate cleaning staff to complete the task.

Providing Services and Facilities. Services and facilities include the following: appropriate management of the cleaning staff (training in appropriate procedures, adequate supervision, stability, wages, acknowledgment of job well-done, and incentive for better performance); sufficient and well-placed hot water or steam outlets; appropriate time to clean and disinfect the equipment properly; adequate design of cleaning equipment (eg, for CIP [flow rate of cleaning fluid], for hard surfaces [cleaning jet design and appropriate temperature and pressure of water]); appropriate design, construction, installation, and maintenance of production plant (see Section 58.3.2); and selecting the appropriate cleaning system and related chemicals.

Providing Appropriate Means to Monitor and Verify the Effectiveness of Cleaning and Disinfection Procedures. This could include swabbing surfaces of equipment after cleaning/disinfection and culturing the residual organisms or using an indirect measure of cleanliness such as measurement of adenosine triphosphate (ATP); testing of food samples produced during the start-up of production; and environmental sampling.[15,24]

Development of Written Instructions. Such instructions should outline the following: cleaning and disinfection procedures; frequency of cleaning; equipment and chemicals needed; quantities of chemical to be used, method for preparation of the required dilutions, and precautions for handling the agents; person responsible for hygiene and monitoring (where direct responsibility is delegated to subordinates, it should be stated clearly who is held responsible); and methods for monitoring the effectiveness of cleaning and disinfection regime. Certain areas or equipment for food preparation may require particular attention because they are critical to the microbial safety or quality of the food being prepared. Such specific information should be included in the sanitation procedures.

Improving Hygiene. This should be considered when: food has been implicated in a foodborne disease outbreak; when stored samples spoil before the expiration date or when a number of spoiled food items are returned by customers; changes in distribution occur requiring longer shelf life; and products do not comply with microbiological criteria established by the producer, customer, or regulatory agency. However, before carrying out hygiene improvements, it is important to consider whether these problems may not have resulted from deficiencies in general hygiene, but from production deficiencies such as times and temperatures used for cooking or cooling or poor storage of raw materials or end-products.[24] Records always should be kept of cleaning and disinfection activities and of results of any tests of their effectiveness.

58.3.5 Selection of Raw Materials and Production Conditions

All operations, from receiving raw materials and ingredients through preparing and processing, to packaging, storage, transport, and distribution, should be conducted in an hygienic way. All reasonable precautions should be taken to ensure that production procedures do not contribute microbiological (and other chemical or physical) hazards to the processed product. Specific consideration should be given to the following:

Starting Materials (Raw Materials and Ingredients). Food manufacturers must be aware of the potential microbiological hazards in starting materials and prepare purchasing specifications accordingly. Such specifications should take into account the microbiological status of the incoming materials, the product's formulation, the process to be applied, and the intended method of distribution and use. Specifications, agreed on between manufacturer and suppliers, are a safeguard for all parties concerned. Compliance with these may be verified by a variety of means, including purchasing the materials under a supplier's guarantee or certification or examination of these materials for microbiological contamination; the use of microbiological criteria in purchasing specifications is discussed in Chapter 65. Raw materials should be inspected and segregated as necessary to ensure they are clean, wholesome, and fit for processing. They should be appropriately handled, disposed of, and stored under good conditions with an effective stock rotation system. Containers and carriers should be inspected on receipt to ensure that their condition has not contributed to the contamination or deterioration of the product. When ice is used in contact with food products, it should be made from potable water and protected from further contamination.

Processing Steps. All food processing steps, including packaging and storage, should be conducted under conditions necessary to minimize the potential for unacceptable survival or growth of micro-organisms or for the cross-contamination or deterioration of the food. This requires the application of suitable processes and procedures to limit microbial growth (eg, chilling, freezing, curing, drying, conserving, fermenting, use of preservatives [see Chapters 5 to 10]) or to kill microorganisms (eg, cooking, pasteurization, sterilization [see Chapters 3 and 4]), and to prevent subsequent contamination (eg, packaging, appropriate warehousing, and storage). Control of such processes and procedures is achieved by monitoring physical factors such as process time/temperature relationships, humidity, a_w, pH, pressure, and product flow rate. Also specific key manufacturing processing operations that may affect the microbiology of the product (eg, heat processing, dehydration, freezing, refrigeration) should be monitored and controlled to ensure that mechanical breakdown, time delays, temperature fluctuations, and other factors do not contribute to contamination or deterioration of the processed product.

Packaging Materials. These should not transmit contaminants and objectionable substances to the products, should conform to regulations and specifications, and should provide adequate protection from contamination. Coding of products should be used, together with appropriate records, to enable lot identification and to facilitate, where necessary, segregation of defective products. Warehousing and shipping conditions should prevent contamination and growth of microorganisms and protect against any undesirable deterioration of the container and the product.

58.3.6 Training and Hygiene of Personnel

Microbiological problems mostly result not from intentionally unsound practices but from ignorance, negligence, or both. It follows that manpower is a crucial factor. The most effective approach to training aims to establish a positive attitude to microbiological quality, product safety, and wholesomeness. Such an approach includes development of knowledge and skills through an appropriate training program. All groups of personnel should be involved, including managers, supervisors, and operators. Many helpful training materials are available from national or international organizations, research or manufacturers' associations, and consultants.[24,41,64] Involvement of the work force is important in hygiene and quality tasks at the production line by, for instance, workers' consultation (eg, hygiene or quality circles), transfer of knowledge, task design (or redesign), feedback of information, autocontrol, and individual commitment to implementation of hygiene management.[17] This also will motivate the staff to maintain or improve their personal hygiene including:

- general personal hygiene
- wearing appropriate clothing and changing and washing of clothes; not using tobacco, or eating, smoking, or chewing while working in a food handling area
- thoroughly washing hands and removing from hand all jewelry that cannot be adequately secured and sanitized
- use of disposable gloves, where appropriate, or washing and sanitizing reusable gloves where they are used
- wearing a suitable hair cover.

It is the responsibility of management to provide the appropriate facilities and instructions and to set an example of compliance with these requirements.

Pre-employment medical examination and periodic re-examination of food handlers for microorganisms likely to be transmitted by food is an established practice in some countries; however, a specialized working group of the WHO,[66] after reviewing health examinations of food handling personnel, concluded that routine examination of food handlers has severe limitations that considerably reduce its usefulness as a control measure. Such examinations, therefore, should have a very low priority and be only target oriented (eg, at persons directly involved in handling ready-to-eat chill stored foods prior to packaging). A more effective, and generally applicable strategy, is to educate food workers on hygienic food handling and to apply appropriate control of food hygiene (eg, by the application of GMP and HACCP).

58.3.7 Documentation

We have already stressed the importance of documentation; all GMP procedures, including sanitation, should be documented and appropriate records of performance maintained. Documentation reflects the commitment of the establishment's management to consistently apply the basic control measures identified in GMPs. Good documentation also demonstrates to third parties that the people responsible for the establishment know and understand their operations and, in particular, how to maintain good hygienic practices in their establishment.

Documentation in GMPs concerned with hygiene should consist, as a minimum, of all core procedures used in an establishment to prevent contamination or adulteration before and during production, the identification of the person(s) responsible for the monitoring and control of the GMP, and records of the actions undertaken to deal with deviations.

58.3.8 Management Commitment

The importance of management commitment to maintain and, where necessary, to improve hygiene standards can never be overemphasized. It is crucial that every company, irrespective of size, should have a coherent policy for achieving the required hygiene standards and directing the appropriate allocation of resources (human, technical, and financial) to achieve this.

58.4 THE HACCP SYSTEM

58.4.1 General Considerations

The HACCP system is a systematic approach to hazard identification, assessment, and control.[24,65] It is primarily intended to be used by food producers to provide them with the ability to meet their responsibility to produce safe and wholesome foodstuffs. Originally it was developed in the United States (US) to provide astronauts with microbiologically safe foods for use on space missions.[3] Since it was first presented at a food safety conference in 1971, its use has been endorsed by governmental and trade bodies throughout the world.

HACCP can be used either prospectively or retrospectively. It is prospective when used during the design of a new product and development of its manufacturing process. It is retrospective when used for validating the safety of an existing process and product. In both cases, it is a dynamic, proactive, and iterative activity aimed at catalyzing or accelerating improvements in product characteristics, manufacturing procedures, and enhancing their control. The expected benefits from its use are improved productivity and reduced consumer risks.

Each specific HACCP study must define the scope of application and take account of any operations before or after the specific operation under study.[9] Visible support and commitment from senior personnel responsible for the food operation under study are essential for the implementation of an effective HACCP plan.[48,49]

There may be some confusion between the process of risk assessment as used by a health authority as part of risk analysis[63] and the use of risk assessment as part of the hazard analysis process carried out within HACCP. It is important to appreciate that the two types of assessment are quite different both in scope and objectives. Thus the process of risk assessment as used by a health authority is a government-led procedure aimed at assessing the health risks to a population or subpopulation, arising, for instance, from the contamination of a foodstuff with a foodborne pathogen. Risk assessment as applied within the HACCP process, on the other hand, is an industry-led procedure, and concerns assessing the probability of occurrence of particular microbiological hazards associated with the production of a foodstuff by a specific process in a particular food establishment. This confusion between the different uses of risk assessment can be avoided by use of "hazard assessment" for the risk-based part of the hazard analysis stage of HACCP.

There are important links between government-led risk assessment and HACCP as shown in Figure 58–2.

First, government-led risk assessment may provide quantitative information on the concentration of a microorganism or a toxin that is potentially of health concern in a foodstuff, and thus provide those concerned with the development of an HACCP plan information on a concentration that must not be exceeded in a marketed food. Second, the outcome of the risk management process (an activity consequential on risk assessment and where options for control of an unacceptable risk are considered) may lead to the proposal of a specific food safety objective (ie, a statement of the maximum level, frequency, or concentration of a hazard in a food that is tolerable in relation to an appropriate level of protection), which may require industry to apply a control procedure during the production of a foodstuff such as a heat process giving a defined reduction in the num-

Next Page

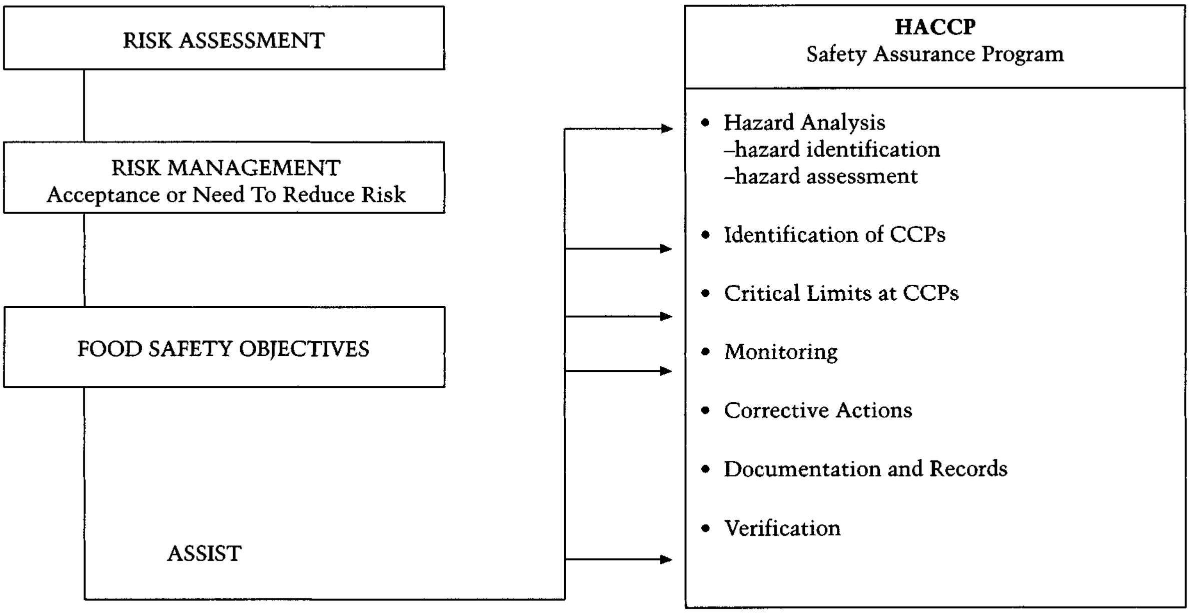

Figure 58–2 HACCP and Risk Assessment

ber of a pathogen. Third, it may provide information on the likely source(s) of microorganisms/toxins in, for instance, raw materials or ingredients.[6,51] Finally, it may provide guidance on the identification of potential critical control points (CCPs) and their control requirements (including verification).

Recognizing that much has been written on the value and application of HACCP (eg, ICMSF*,[24] NACMCF*,[46,47] CFDRA*,[9] IAMFES*,[23] Bryan,[5] Pierson and Corlett,[54] Mortimore and Wallace,[44] ILSI[31]) and there is an internationally agreed-on approach to establishing and applying HACCP, proposed by the Codex Alimentarius Commission, the latter will be used as the main basis for the following sections on HACCP.

58.4.2 Use of the Codex Alimentarius Approach to HACCP[12]

The main features of this approach are that it sets a framework for the use of HACCP that is applicable throughout the food chain, it provides an internationally accepted glossary of terms (see Exhibit 58–2), and it enunciates seven key principles or steps in setting up an HACCP plan.

These principles are:

1. Conduct a hazard analysis
2. Determine the CCPs
3. Establish critical limit(s)
4. Establish a system to monitor control of the CCP
5. Establish the corrective actions to be taken when monitoring indicates that a particular CCP is not under control
6. Establish procedures for verification to confirm that the HACCP system is working effectively
7. Establish documentation concerning all procedures and records appropriate to these principles and their application.

It also provides guidance for the application of these principles based on a sequence of 12 activities. These are:

1. Assemble an HACCP team
2. Describe the product
3. Identify the intended use
4. Construct a flow diagram
5. Carry out onsite confirmation of the flow diagram
6. List all potential hazards associated with each

Exhibit 58–2 Glossary of Terms Used in HACCP

Control (verb): To take all necessary actions to ensure and maintain compliance with criteria established in the HACCP plan.
Control (noun): The state wherein correct procedures are being followed and criteria are being met.
Control measure: Any action and activity that can be used to prevent or eliminate a food safety hazard or reduce it to an acceptable level.
Corrective action: Any action to be taken when results of monitoring at a CCP indicate a loss of control.
Critical control point (CCP): A step at which control can be applied and is essential to prevent or eliminate a food safety hazard or reduce it to an acceptable level.
Critical limit: A criterion that separates acceptability from unacceptability.
Deviation: Failure to meet a critical limit.
Flow diagram: A systematic representation of the sequence of steps or operations used in the production or manufacture of a particular food item.
HACCP: A system that identifies, evaluates, and controls hazards that are significant for food safety.
HACCP plan: A document prepared in accordance with the principles of HACCP to ensure control of hazards that are significant for food safety in the segment of the food chain under consideration.
Hazard: A biological, chemical, or physical agent in, or condition of, food with the potential to cause an adverse health effect.
Hazard analysis: The process of collecting and evaluating information on hazards, and conditions leading to their presence, to decide which are significant to food safety and therefore should be addressed in the HACCP plan.
Monitor: The act of conducting a planned sequence of observations or measurements of control parameters to assess whether a CCP is under control.
Step: A point, procedure, operation, or stage in the food chain, including raw materials, from primary production to final consumption.
Validation: Obtaining evidence that the elements of the HACCP plan are effective.
Verification: The application of methods, procedures, tests, and other evaluations, in addition to monitoring, to determine compliance with the HACCP plan.

step, conduct a hazard analysis, and consider any measures to control identified hazards
7. Determine CCPs
8. Establish critical limits for each CCP
9. Establish a monitoring system for each CCP
10. Establish corrective actions
11. Establish verification procedures
12. Establish recordkeeping and documentation.

This approach is very similar to that recommended by the NACMCF[46] and has served as a common format for most other contemporary descriptions of HACCP.[9,31,64]

The following sections will consider in turn each of the 12 activities recommended by Codex for the application of HACCP.

Assemble HACCP Team

The design of an HACCP system for a particular product requires a multidisciplinary team approach. The scope of the study influences the composition of the team that should include the range of experience and in-house, or where necessary external, expertise to properly carry out the activities identified. According to the particular study, the team might include a production specialist responsible for, or directly involved in, the process under study; an engineer (with knowledge of the technical performance of any processing equipment and aspects of design that may affect product hygiene); a quality assurance/quality control specialist; and other relevant experts (eg, a food microbiologist with specific knowledge of the microbiological implications of the particular processing operations). A team leader should be nominated to guide the discussions and a secretary to record the decisions. For small organizations, it may be appropriate for one person to fulfill more than one role provided that the team is capable of obtaining and using relevant information to identify the hazards potentially associated with a particular production operation, to assess their significance, and identify options for their control.[9,23,44,46,47,63] For some companies, this may prove difficult or impossible, and, in the absence of suitable in-house expertise, a third-party organization may need to be used to provide the required level of expertise to develop a valid HACCP plan.

Describe Product

Such description should include the raw materials and the final product. For each raw material used, collect data on the type, source, purchasing specifications, and its percentage use in the final product (see below). Also any procedures or treatment(s) applied before receipt, conditions of storage, and additional data such as pH or a_w of the raw materials should be recorded. The final product, or intermediate products as necessary, should be defined in terms of composition, structure, processing conditions (eg, heat treatment), intrinsic factors affecting stability (eg, pH, a_w, preservatives), packaging, storage and distribution conditions (temperature in particular), shelf life expectations, package labelling, and instructions for use. A useful system for collecting and recording such information is illustrated in Exhibit 58–3.

In this system, for each raw material used, data are collected on its type, its percentage in the final product, conditions of storage, and additional data relevant to its microbiological stability such as pH and a_w. For each process operation, data are collected on the type of operation, the equipment used, the product and environment time/temperature, and additional information on the equipment such as materials of construction. The information in the boxes can be linked together to indicate product flow(s) and to form a detailed outline of the process.

Identify Intended Use

The intended use should be based on the expected uses of the product by the end user or consumer. In addition, it is necessary to take into account the possibility of exposure of the final product to temperature abuse by the purchaser and the likelihood that it will be consumed by vulnerable groups of people including infants and children, pregnant women, the elderly, or people with impaired health.

Construct Flow Diagram

Description of the process requires the preparation of a process flow diagram. The diagram should cover the whole operation from the selection of raw materials through the processing, packaging, final storage, and distribution stages and show the breakdown of the process in each constituent step. The flow diagram should be accompanied by specific technical information. These may include factory, line, and equipment lay-out; flow conditions of products, including delays during or between steps, recycle or rework loops, and transfers between steps; routes of mobile materials, equipment, and utensils; air flow and water flow; personnel routes; and segregation of any low- or high-risk areas.

In addition, for each process operation, data should be collected on the type of operation and its technological function (eg, effect on microbial flora and numbers), equipment characteristics (eg, size, capacity, existence of void space), operation parameters, product and environment time and temperature conditions, cleaning and disinfection procedures, and environmental and personnel hygiene.

A conventional flow diagram containing the type of information that should be recorded is illustrated in Figure 58–3. This type of diagram can be used to record the information described above or the flow diagram can be built up from the series of boxes illustrated in Exhibit 58–3.

Carry Out Onsite Verification of Flow Diagram

The flow diagram should accurately reflect the actual processing operation. For an existing product/

process, the collection of information must be carried out under production conditions and require close observation of all stages, including any night shift or weekend running. A final onsite confirmation during hours of operation will provide an appropriate verification of the data collected.

Where a new product development is under evaluation, data representing the product definition and the most likely processing options are provided by the departments involved in the development.[24] These will require confirmation and may possibly need some revision when the product is finally put in to production. Carrying out a preliminary HACCP at an early stage of product development will identify the main potential CCPs and highlight control needs.

Perform a Hazard Analysis

Hazard analysis is the process of collecting and evaluating information on hazards associated with a particular food that are potentially of health concern (together with any specific conditions potentially leading to their presence at health concern levels), to decide which are significant for food safety and, therefore, should be addressed in the HACCP plan. Hazard analysis, therefore, includes two stages: hazard identification and hazard assessment.

When developing a safety assurance plan, all potential biological, chemical, or physical hazards associated with any step, point, or procedure in the process need to be identified by mean of a stepwise investigation. The current discussion, however, will focus only on microbiological hazards and include spoilage as well as health concerns.

Hazard Identification. Microbiological hazard identification encompasses a listing of all types of microbiological hazards relevant to the product under consideration and the specification of the conditions (eg, failure to control a particular raw material or processing step) leading to the presence of microbiological contaminant(s) at hazardous levels (ie, levels that are likely to cause illness or spoilage). Such conditions may occur at any stage in the food operation under study resulting in the growth or survival of an organism or toxin in a foodstuff or the contamination or recontamination of a raw material, intermediate, or final product.[31]

Listing of Types of Microorganisms and Microbial Toxins. Both food poisoning and spoilage microorganisms (and their metabolic products) are of concern, although only pathogens and toxins would be considered in a specific safety assurance plan. An appreciation of those hazards that are relevant to the product and process under consideration is the natural starting point of a hazard analysis. It is also the most difficult part of the analysis because unless this activity is done thoroughly, using knowledgeable people with appropriate understanding of the food operation under study, the subsequent decisions on product safety requirements may well be flawed. Thus, this step requires microbiological knowledge of the physiology of microorganisms of potential concern in the foodstuff, and specifically the influence of intrinsic, extrinsic, and implicit factors relevant to the food; processing; storage and use conditions; their destruction, survival, or growth; or their ability to form toxins and the resistant characteristics of these.[26,45] It also requires knowledge of the microbial ecology of raw materials used, the factory environment, and products (information that may only be obtained by a microbiological investigation carried out on the actual plant). Also needed is technical information on the major processes, any epidemiological information indicating whether a given product or a similar product has been implicated in foodborne disease and the type(s) of microorganisms involved, and commercial or other information (such as results of challenge testing or storage trials) on the microbiological stability and safety of the product.

All this information is used to determine which microorganisms the study needs to consider. Starting with a list of known pathogens (and spoilage microorganisms where relevant), the exercise consists of selecting relevant microorganisms and toxins likely to be of concern. It may be possible to group together similar organisms of concern and use one organism that is representative of that group on the grounds of similar physiology and survival characteristics. The chosen organism should be a likely contaminant and be most resistant to the conditions used in production and, where appropriate, able to grow in the final product. Other important points to consider in selection of microorganisms of concern are:

- the type (and number) of microorganisms expected to be present in raw materials
- the type (and number) of microorganisms likely to be introduced during handling or processing
- the effect of processing or handling, including consumer practices such as preparation for consumption, on their growth, survival, or death
- the target group(s) of consumers.

It is most important that all relevant potential hazards be identified without regard to their probability of occurrence or their severity. For instance, although botulism is properly controlled by the thermal process used by industry for the manufacture of low-acid canned foods, when embarking on an HACCP study of such a process, a food producer should always list *Clostridium botulinum* as a potential hazard for such type of production. This will allow the HACCP team to decide, as the analysis proceeds, whether the conditions of production and the status of controls currently in use are satisfactory or need improvement. A similar reasoning applies also to new or emerging pathogens such as verocytotoxin-producing strains of *Escherichia coli*, which need to be included in HACCP studies of ecologically relevant products. Where microbiological specifications have been developed for a foodstuff (particularly if these have been based on a risk assessment), they may be used as an aid in identifying microorganisms of concern for that specific foodstuff and the level to which they should be controlled. However, hazard identification should not only be limited to those microorganisms covered by existing specifications but should include consideration of all relevant foodborne pathogens, toxins, and spoilage microorganisms.

The HACCP team should examine systematically the particular microorganisms or microbial toxins that may affect the safety or "keepability" of the product(s) under consideration. In this way, a list of likely microbial hazards, based on known information, is obtained.

Conditions Leading to the Presence of Microorganisms and/or Microbial Toxins. For each identified hazard, the analysis then proceeds with the identification of situations where the hazard(s) listed under the previous section could be introduced into the production process. The exercise is done stepwise for each raw material and ingredient and for each step in the operation, including packaging, storage, and distribution, using the process flow diagram as a guide. Thus each raw material or ingredient is evaluated for the likely presence of microorganism(s) and/or toxin(s) identified to be of concern.

Each processing or food handling step identified in the flow diagram is systematically and specifically considered in sequence as to its possible role in creating or controlling a microbiological hazard. This would include the effect of possible delays during and between processing steps, rework loops, and conditions of transfer from one step to the other on the growth of microorganisms of concern. Also, the potential at each step for contamination (or recontamination) or process failure leading to survival of hazards of concern is systematically evaluated.[42] As the analysis proceeds, the likely conditions and causes leading to the realization of these hazards are recorded and, as far as possible, the effect of these on microbial numbers quantified. During these activities, the HACCP team should consider not only what could happen under normal operating conditions, as recorded in the process data collected, but also under realistic process variation, malfunction, drift, or misoperation at any step in the production process. For each of the hazards considered, this leads to a listing of conditions under which a significant hazard could occur for all raw materials and processing steps throughout the food operation under study.

Several tools or techniques can be used to structure and quantify the process of hazard identification, including the use of standard questionnaires such as those proposed by bodies such as ICMSF,[24] IAMFES,[23] and NACMCF,[46] and quality improvement tools developed by quality assurance specialists. Among the latter, cause and effect analysis[39] has been found to be useful. This considers, during a brainstorming session, the relationship between different categories of possible causes and a given effect (eg, insufficient heat treatment and microbial survival). Five major categories of causes may be investigated in this exercise (ie, the environment, equipment, production methods [including process parameters and measurements], food materials, and personnel). Each category of major cause is analyzed and brainstormed to focus-in on more and more specific causes. Other structured, reliability analytical techniques include Fault Tree Analysis,[39] Failure Mode and Effect Analysis,[3] and HAZOP;[2] the latter has been found to be particularly valuable for structuring microbiological hazard analyses.[42]

Other useful data can be obtained by measurements of temperature, pH, and a_w of the product and testing of product and environment samples for microorganisms.[5,23] Also the use of challenge testing,[53] predictive microbiology, and related software (see Chapter 16) will provide further additional information on conditions likely to lead to a microbiological hazard.

Hazard Assessment. Hazard identification results in a list, identifying for each microbiological hazard the conditions leading to its occurrence. While clearly all such hazards and condition(s) under which they may occur should be appropriately controlled, to decide the degree to which resources should be applied to their control, it is necessary to decide which of the identified hazards will significantly affect the safety or wholesomeness of the final product. Such a hazard assessment should take into consideration two factors: the frequency or probability of occurrence of a condition(s) that could result in the hazard(s) occurring, and if these occur, their seriousness in terms of adverse health effects or a spoilage concern. Thus, the expected outcome of such an assessment is a ranking of the significant hazards, a listing of the condition(s) that could lead to their occurrence, and the likely frequency and seriousness of such an event if it occurred. This information is to be used when control setting, determining priorities for action, and specifying the stringency of control required.

The frequency of occurrence of a hazard relates specifically to how the conditions applied during a food operation lead to the presence of the hazard in the final product. For instance, the presence of salmonella in a dry milk powder is a general cause of concern for this type of product, and salmonella would be expected to occur in any listing of relevant hazards to be considered in an HACCP study of a dry milk plant. After identifying the conditions leading to the potential presence of Salmonella in the specific production operation under study, it is then necessary to assess the probability of occurrence of such conditions. Assessing such probability consists, basically, of answering two questions. First, does the condition leading to a significant hazard occur only very occasionally, or, conversely, is it an ordinary or usual situation? Second, as a result of the condition occurring, will the hazard concerned be present only occasionally in the final product, and how often, or will it be regularly present?

Such frequency estimation is ideally based on the number of times the condition leading to a hazard occurring has actually been observed to occur (ie, based on a documented history of processing successive food lots). In the absence of such information, an estimate or probability of occurrence should be made based on the best information available on the occurrence of the hazard and likelihood of the condition that could lead to its occurrence during expected production conditions. Such an assessment, if based on observed frequency, may be quantitative but is more often characterized by a qualitative scale such as high, medium, or low or definite, likely, or remote. Such an estimation should be based on technical information and expertise and will often require the use of brainstorming or some other investigative technique to obtain the best estimate.

Determining the severity or gravity of a hazard requires two considerations. The first is to consider, for each identified microbiological hazard, the consequences of the occurrence of each hazardous condition on the types and numbers of microorganisms or metabolites that could be present in the final product. For example, the number of pathogenic or spoilage microorganisms originating from a raw material that are likely to be present in a final product may depend on the formulation of the product, the effect of subsequent processing steps, and line or environment cross-contamination by raw materials. Also, the effect of process inadequacies or failures on type and numbers of microorganisms should be considered, as well as in- or post-process contamination, mishandling during storage, distribution, retail display, or consumer use. Predictive microbiology can be used to simulate the effect of these possible deviations on microbial growth or survival—provided the conditions arising from them can be measured or estimated; the use of such simulations is discussed in Chapter 65. All of this will provide information on hazard occurrence in the final product.

The second, and most important consideration, is an appreciation of the significance of the occurrence of a hazard. Will it result in damage to the consumer? What is the gravity of the disease arising? Alternatively, are the consequences trivial or insignificant in terms of foodborne disease or product spoilage? Where there is a need to meet a legal or customer-specified microbiological criterion, will this lead to nonconforming lots?

To reach a meaningful decision on the severity of a hazard, human and technical factors need to be taken into consideration (eg, the target consumer group). For instance, considering our example of salmonella in dry milk, salmonellosis is a severe disease for the population at large. However, the consequences of the presence of salmonella in dry milk would be of even greater concern, and hence severity, if the product is specifically intended to be used for feeding infants.

Severity of a hazard should be quantified as far as possible, taking account of the considerations listed above. However, very often severity can only be expressed qualitatively as high, when directly resulting in the potential of an unsafe or otherwise unacceptable product; major or moderate, when reducing the acceptability of a product for its intended purpose; and minor, when it is not likely to reduce usability.

The qualitative and, where possible, quantitative assessment of frequency of occurrence of a hazard and an estimate of its severity are finally used to rank, according to degree of concern, the process stages, practices, or procedures that potentially could lead to a hazardous situation(s) or condition(s).

Ranking usually is expressed by such terms as "critical," "major," or "minor" concern. Specific techniques, such as the use of failure mode, effect and criticality assay,[8,39] can be used to structure this activity.

Determine Critical Control Points

The process and conclusions of hazard analysis allow identification of places in the food operation where hazard-causing situations may occur, together with their degree of concern. The need now is to handle this information to decide on how to manage such situations.

Having first checked that GMP requirements are in place, the HACCP team then should consider what additional control measures (if any) are required. One decision that may arise is the possibility of totally eliminating a hazard or of reducing the impact of a hazardous situation or condition by introducing changes in the product or in the process. This may require changing the form or source of a raw material or ingredient; changing the formulation of the product, such as the introduction of new microbiological barriers; changing a step in the manufacturing process or its processing parameters; modifying the conditions of packaging or distribution; or modifying the instructions for preparation for consumption.

The control of the remaining hazardous conditions is based on the use of the concept of a CCP. This can be defined as a step at which control is essential to prevent or eliminate a food safety hazard (identified by the previously described process of hazard analysis) or to reduce it to an acceptable level.[12] The rationale behind the identification of a CCP is that if an operation is faulty and/or monitoring inefficient at this point, this will result in a major concern and a high probability that a severe, direct health hazard or a high level of spoilage will occur. On the contrary, if a CCP is properly controlled and monitored, it will provide a high degree of confidence that the identified hazard will be effectively controlled.

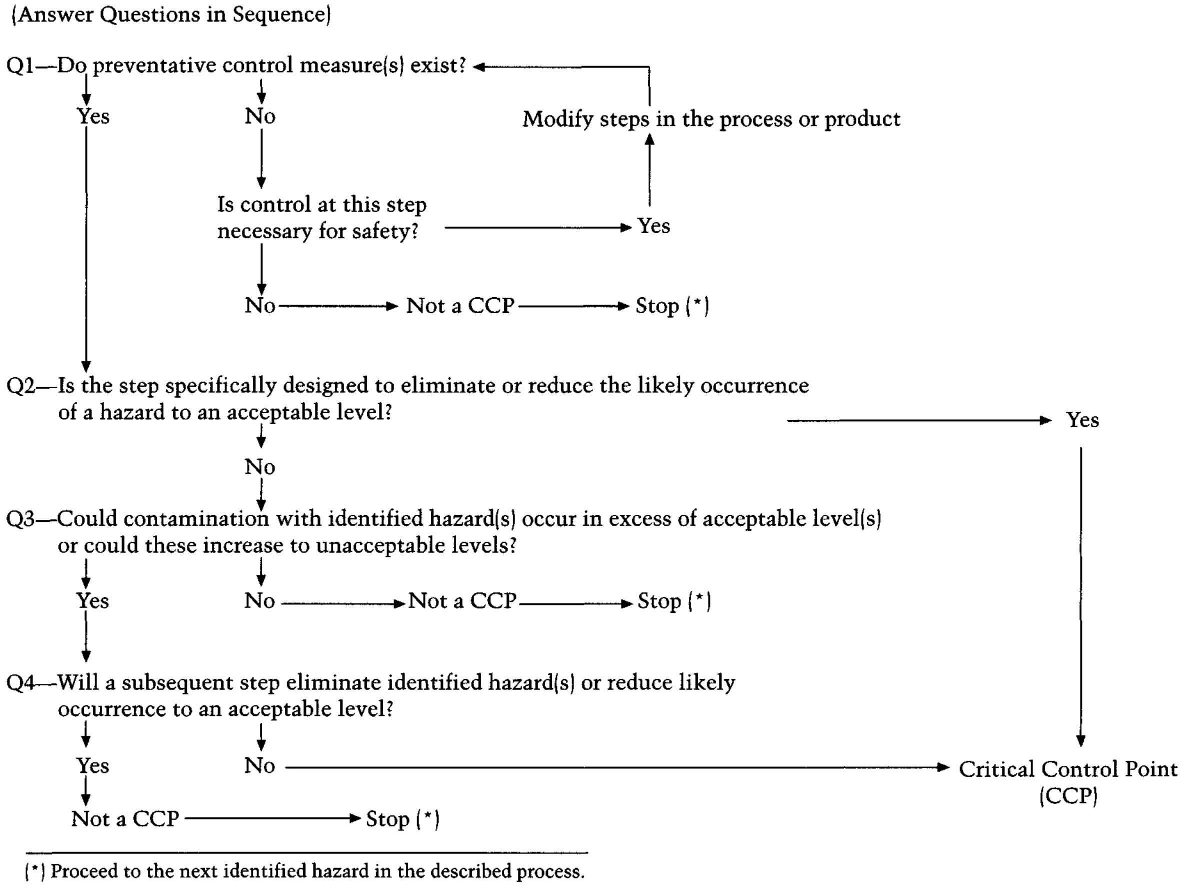
To be effective, CCPs have some basic characteristics.[59] First, they must be specific points where control is necessary to avoid the occurrence of one or more hazards. Second, operational means must be readily available for their control and at a reasonable cost. Such means can be directed toward eliminating a microorganism of concern or reducing its number to an acceptable level (eg, use of pasteurization to kill infectious disease-causing pathogens such as salmonella in milk and to increase the shelf life of milk) or preventing a hazardous condition from occurring or reducing its impact (eg, by acidification or refrigeration of a product to slow or prevent microbial growth). Finally, they must be capable of being readily and reliably monitored. For example, they could be monitored by visual means such as observation, by physical means such as measurement of pH or temperature, or by chemical means such as monitoring the level of chlorine in the water used for cooling canned food after a thermal processing.

CCPs are established with specific regard to each significant hazard identified. In many instances, they correspond directly to a step, practice, or procedure from which a hazardous condition may arise if control is lost. In some instances, direct control of a hazardous condition where it occurs is not possible, is difficult to achieve, or effective monitoring is not feasible. In such cases, the possibility of establishing CCPs further in the process should be considered. For instance, in the canning industry, avoidance of understerilization is achieved by appropriate control of temperature and time of the sterilizing process. After sterilization, it is necessary to ensure that recontamination (a hazardous condition) cannot occur. Recontamination can occur as a result of the presence of minute holes in the sterilized container and organisms being drawn into the container during cooling. Although the sealing process, applied to the container prior to sterilization, is a CCP, it is difficult to control this process such that no holes in the seams or seals of the containers occur; also monitoring techniques are not able to guarantee that all containers are free from holes. Therefore, CCPs must be established after sterilization to prevent contamination entering the container and contaminating the product. Control measures include chlorination of the water used for cooling the containers and the avoidance of manually handling the containers while they are hot.

Identification of CCPs requires a good understanding of the food operation, technical expertise, and expert judgment. To facilitate this task, it may be advantageous to use "decision trees" as guidance. Examples of decision trees aimed at identifying CCPs can be found in the literature.[12,31] One such decision tree, developed by a working group set under the auspices of the Codex Alimentarius Food Hygiene Committee, is illustrated in Figure 58–4.

In this decision tree, for each step in the process with identified hazard(s) (starting with the raw materials and proceeding stepwise throughout the process), each of the four questions listed in Figure 58–4 is considered and answered in sequence.

While there is no lower or upper limit to the number of CCPs that can be identified in a process, it is always wise to keep the number of CCPs to a minimum to keep the system "user friendly"; always remember that general hygiene requirements are con-



(Answer Questions in Sequence)
Q1—Do preventative control measure(s) exist?
Yes
No
Modify steps in the process or product
Is control at this step necessary for safety?
Yes
No
Not a CCP
Stop (*)
Q2—Is the step specifically designed to eliminate or reduce the likely occurrence of a hazard to an acceptable level?
Yes
No
Q3—Could contamination with identified hazard(s) occur in excess of acceptable level(s) or could these increase to unacceptable levels?
Yes
No
Not a CCP
Stop (*)
Q4—Will a subsequent step eliminate identified hazard(s) or reduce likely occurrence to an acceptable level?
Yes
No
Critical Control Point (CCP)
Not a CCP
Stop (*)
(*) Proceed to the next identified hazard in the described process.

Figure 58–4 Example of Decision Tree To Identify Critical Control Points. *Source:* Reprinted with permission from *Food Hygiene—Basic Texts*, p. 44, © 1997, U.N. Food and Agriculture Organization.

trolled as part of GMP. Check that CCPs initially identified are not redundant (ie, although control of a particular step appears necessary to prevent a hazardous condition arising such as the potential for an acceptable growth or survival of a foodborne pathogen, and is therefore a CCP, a later step in the process may also provide effective control, and is also a CCP, making the first CCP redundant). This duplication of CCPs should be avoided by following the logic sequence of questions in Figure 58–4. Further CCPs may be eliminated by introducing changes in the product or process; in addition to reducing the number of CCPs, this can often also make the product safer.

If an analysis suggests that a potentially critical hazardous condition cannot be controlled at a certain step in the process or production operation, and no later CCP will give effective control, this should trigger modification of the step (eg, equipment or procedure) or the reformulation of the product to introduce a CCP.

It cannot be overemphasized that CCPs are highly specific to a given product and the conditions used for its production; they must not be applied to another food operation without first checking, by way of a hazard analysis, that they will apply. Any change in the product/process also should trigger a new hazard analysis and, if necessary, the revision of the list of CCPs. Due to such specificity, CCPs listed in so-called generic HACCP models (ie, HACCP models developed for the manufacture of a particular commodity or food product and not related to a particular plant or specific manufacturing operation) may be totally misleading and reduce the flexibility inherent in the proper use of HACCP. Their use should, therefore, be generally discouraged and avoided except for their possible use for illustrative purposes in general hygiene codes, in which cases their purpose must be clearly stated and the reader warned not to apply them to a particular operation without first performing a hazard analysis.

For each CCP, the control measures that can be applied for each hazard have to be identified and documented. These are intimately associated with the concept of a CCP. They refer to the techniques and activities that give the CCP its function in preventing or eliminating a hazard or reducing it to acceptable level. The control measures at each CCP should be selected in terms of effectiveness and utility. This principle can be illustrated with reference to the control measures applied to ensure the microbiological acceptability of pasteurized ham. Here, design and maintenance of equipment and operational control (eg, time and temperature of processing and hygienic handling of cans postprocessing) are more effective (high success and low cost) than sampling and testing for indicators of underprocessing or postprocessing recontamination (low success and high cost).[2]

Also effective control of the raw material supply, where a raw material is identified as a CCP, should include supplier approval, based on the supplier's safety assurance plan (HACCP-based) and an established quality assurance program. This will give much greater assurance that a delivery of a raw material is acceptable for use rather than relying on testing on receipt; for information on the confidence of decisions based on microbiological testing and on the application of microbiological criteria, see Chapters 60 and 65 respectively.

Establish Critical Limits for Each CCP

A critical limit is defined as a criterion that separates acceptability from unacceptability.[9] The purpose of a critical limit is to provide a basis for the acceptability of control applied at a CCP. Such definition and purpose have three crucial implications for the management of a CCP.

First, a critical limit marks the absolute tolerance of a control measure applied to a CCP and should never be exceeded. When a critical limit is exceeded, the CCP is out of control and the product is likely to nonconform (eg, potentially a safety concern or having nonconformance with pre-established specifications). When day-to-day values are used (eg, target values or tolerances), they should always be established within the critical limits and be so designed that they ensure that the critical limits will not be transgressed, while taking into account normal process variations and measurement errors. For instance, a pasteurizer in a milk plant could be operated so that the milk is pasteurized at a target temperature of 73° C and held at this temperature for 15 seconds. The critical limit for this process is to heat the milk to a temperature of 71.5° C for 15 seconds, which is the generally accepted minimum limit for high temperature short-time pasteurized milk. However, the plant is operated at the higher temperature so that no milk will be pasteurized at a temperature below the critical limit.

Second, a critical limit should be quickly and easily observed or measured and provide a yes/no response. Thus where control of a microbiological concern is the intent, it is preferable to use a physical or chemical parameter as a critical limit rather than a microbial concentration because the latter often is difficult to measure accurately (see Chapter 60) and the results of an analysis slow to obtain. Parameters that can provide good information on the state of control of microbial hazard include physical parameters such as time, temperature, humidity, moisture level, a_w, and pH, and chemical parameters such as titratable acidity, salt concentration, available chlorine, viscosity, and concentration of preservatives. They also may include the use of behavioral (eg, compliance with a specific food handling procedure) or sensory parameters (eg, visual appearance, texture, aroma). Although critical limits based on direct microbial numbers are not generally useful for reasons stated above, where very rapid measurements can be made (eg, ATP bioluminescence to monitor cleaning effectiveness or impedance measurement to monitor total levels of microorganisms in raw materials), the related parameter can be used to set critical limits.

Third, a critical limit, in order to be significant, must be coherent with the microbiological requirements (including microbiological specifications) defined for the final product. Only by taking into consideration such requirements can appropriate critical limits be identified at a single processing step, a sum of steps, or even for the whole process. Evidence of such relationship should always be established and provided. To that aim, the microbiological requirements for the product produced by the operation to which the HACCP plan is under development should be known or agreed to in advance by the HACCP team. Such microbiological requirements may be expressed as a performance criterion (eg, a specified reduction in microbial numbers such as the 12D concept applied for the destruction of *C. botulinum* in low-acid canned foods), a process criterion (eg, the time and temperature used to reduce *C. botulinum* by 12D), or a microbiological criterion (eg, a limit for a concentration of a given microorganism or toxin in a product); the relationship between these different types of criteria is discussed in Chapter 65.

Critical limits can be derived from many sources: a risk assessment; research; scientific and technical literature; computer simulation; in-house experiments; supplier's records and data; expert advice and consultancy; guidelines from international organizations; and regulations. For existing products, limits already in place should be assessed and validated prior to their use in the detailed HACCP plan. Where necessary, a change in parameters and/or values may be introduced.

Establish a Monitoring System for Each CCP

Monitoring is the scheduled measurement or observation of a CCP relative to its critical limit(s).[12] The rationale for monitoring is to provide evidence that critical steps or procedures (ie, CCPs) are kept under control and that, should an out-of-control situation occur, it can be readily identified so that corrective action can be taken rapidly. It involves the scheduled observation or measurement of significant components or parameters at CCPs, to assess whether they are under control.

Monitoring should aim to identify an out-of-control situation at a CCP before start-up or during production. Ideally, systems should be in place that monitor control at CCPs continuously, online and in real-time, thus providing immediate and automatic adjustment as necessary. Most frequently, however, only discontinuous and/or offline monitoring systems can be used. For such, it is necessary to ensure that the frequency of observations and/or sampling should be statistically valid. Whenever practical, statistical process control techniques should be used to enable objective decisions for corrective actions to be reached; see Chapter 60.

Monitoring techniques have been reviewed extensively.[24] As noted previously, visual observations, sensory evaluation, and physical or chemical measurements are best suited; microbiological methods (except the very rapid ones, eg, ATP bioluminescence) are not appropriate for monitoring. Microbiological methods are nevertheless invaluable for investigating a process and may be useful for verification purposes; see Chapter 65.

The monitoring procedures should be fully documented with indication of the CCPs to which they apply, the characteristic(s) to be monitored, the frequency of monitoring, the method(s) to be applied, and the person responsible for approval of the records and for decisions on corrective actions. Full records must be kept of all monitoring data and the person responsible for circulation of information and records should be specified.

Establish Corrective Actions

Corrective actions are the actions to be taken when the results of monitoring indicate that the operation at a CCP fails to meet the critical limit (ie, a situation where control is lost leading to a hazardous condition). Such corrective actions need to be identified in advance and laid down in a corrective action plan.

The primary concern if a CCP is outside its critical limit is that the manufactured product does not, or may not, meet the specified requirements for safety. Hence, the corrective action plan should always document disposal of the suspect product—including identification, segregation, review, and appropriate disposition. This supposes some system of traceability and, in the case of products that have immediate delivery, an emergency or recall plan. The ISO 9004 standard[37] provides appropriate information and guidance on all such actions.

Another concern, of equal importance, is to prevent recurrence of the deviation that led to the critical limit being exceeded. This implies immediate action to adjust the processing or other conditions to bring the CCP back within its critical limit(s). It also requires a proper identification of all factors affecting the capability of the process to at all times meet the critical limits. Ensuing decisions are essentially based on the severity of the potential deviation that could occur. In a very high-risk situation (very high impact on food safety), it may be deemed necessary to stop the process until the problem is fully corrected. Otherwise, after adjustment of the process, specific additional monitoring or routine checks should be made to confirm that adjustment is effective in maintaining control. Should deviations occur with high frequency or control prove difficult to maintain, this should trigger, in addition to emergency corrective actions, verification and review of the HACCP plan. For effective prevention of problems caused by process drift, corrective actions to adjust the process before the drift leads to transgression of critical limits should always be carried out. Corrective actions should be fully documented and records kept on occurrence and actions taken.

Establish Verification Procedures

Once implemented, the HACCP plan and the resulting HACCP system should be evaluated on a regular basis. Within the HACCP methodology, this specific process is called "verification." Verification should be carried out primarily by the operator to confirm that the various elements of the HACCP plan are in place and the HACCP system derived from the plan is fully functional and provides the degree of assurance specified in the plan.

In contractual or regulatory situations, verification of the HACCP-based safety assurance plan also can be carried out by the customer or by a public authority to determine the ability of the food producer to meet specified requirements. The current discussion will focus on verification as used by a company for internal purposes. Several objectives may be involved in the process of verification. These include checking a plan prior to implementation, assessing whether a plan is properly implemented (ie, the HACCP system conforms with the HACCP plan; this preimplementation check may be called validation), determining whether a plan and system are functioning effectively, or reviewing the HACCP plan and system to decide on appropriate modification(s).

The frequency and extent of verification will depend on the evidence that leads the operator to conclude that the system is functioning properly. Thus, on implementation of a plan where there will be no evidence of proper functioning of a system, verification should always be carried out. As documented evidence of satisfactory functioning of the system is obtained, the frequency of verification can be reduced. Review of an HACCP plan should follow:

- frequent occurrence of process deviations
- receipt of information from the market indicating a health (or spoilage) problem
- when epidemiological or scientific information identifies new hazard(s) of concern
- when commercial information indicates changes in distribution systems or consumer's use or when anticipating such change
- prior to (rather than after) introducing changes in product/process conditions (eg, new raw material/product to be used, formulation to be changed, new processing technology/equipment to be used).

The basic technique for verification is to audit the HACCP plan and system or part of it. The procedures encompass all or part of the following.

Pre-audit Documentation Review. This would include review of documentation on GMPs (eg, hygiene measures in place, cleaning programs, personnel hygiene and training), HACCP documentation, and records.

Onsite Audit. This would include confirmation of product description, facility layout, and flow diagram; confirmation of hazards as identified; assessment/confirmation of CCPs; review of control options and critical limits and of their effectiveness; and confirmation of monitoring activities and of their effectiveness; review of adequacy and effectiveness of corrective actions; confirmation of the existing verification procedures.

Additional Verification Procedures. This could include, as necessary, collection and microbiological analysis of samples from CCPs or other appropriate points and storage tests on products (for instance, from a recently installed operation) or increased end-product testing. When the latter is considered, special attention should be given to the practicability of the microbiological methods involved and, more importantly, whether the microbiological quality level can be accurately assessed by a feasible sampling plan. Due to the statistical limitations of end-product sampling and testing,[20,24,25] once an HACCP plan has been properly designed, implemented, and appropriately verified, routine microbiological testing of end-products will serve little purpose and is therefore not recommended.

Audit Follow-Up. This would include the use of specific procedures to verify that the recommended changes have been introduced into the HACCP plan and satisfactorily implemented. The general questions that should be asked by an auditor, when verifying a HACCP system, are listed in Exhibit 58–4.

Establish Record Keeping and Documentation

Adequate documentation is essential to provide evidence that all issues relevant to the scope of the HACCP plan have been addressed, and controls properly designed, implemented, monitored, and verified. The documentation system involves three elements.

Documentation of the HACCP Plan. Documentation includes scope of plan; composition of the team involved and assigned responsibilities; description of raw materials, intermediate and final products, and their specifications; facility layout and flow diagram of the process; hazards identified (and reasons); CCPs identified; management of each CCP, including control measures, critical limits, monitoring activities, and corrective action plan(s); and verifica-

Exhibit 58–4 General Questionnaire for Use in HACCP Verification

Name of Plant: ____________________ **Date of Review:** __________________ **Name(s) of Reviewer:** _____________

Information To Be Reviewed: Much of the following information can be obtained prior to a review and verified on the plant visit by reviewing records and talking to those responsible for the HACCP plan(s), the plant operatives, and the plant management.

- Who is on the HACCP team? Who is the HACCP team leader?
- What are qualifications/experience of the team members?
- Has a member of the team attended an HACCP training course?
- Is there a documented HACCP plan for each process?
- Is there a flow diagram for each process?
- Is there a plant layout available? If so, do the product, process, and people flows within the plant minimize the possibility of microbial cross-contamination?
- Select an HACCP plan and review the process flow. Does it agree with the HACCP plan?
- Who were/was responsible for identifying the hazards and the CCPs in the particular HACCP plan(s) under review? Are the reasons for the choice of these documented? Are they soundly based? Have critical limits been established for each CCP? Who established the limits? What rationale was used for establishing these limits and their associated monitoring procedures? Are these soundly based?
- Who monitors a CCP? Is monitoring done according to the HACCP plan? Are the results properly recorded? Who verifies that the CCPs are monitored correctly? Do the operators know the critical limits and what to do to prevent a deviation from occurring (or is this done automatically)?
- What happens when a deviation occurs? Is a plan (documenting corrective actions) in place to address deviations? How is management notified of a deviation? Are all corrective actions undertaken when a deviation occurs properly recorded in a deviation log book or as a similar centrally maintained record? Who approves a change in a CCP, a critical limit, a monitoring procedure, or a corrective action? Are all changes approved, documented, and properly communicated to operatives, supervisors, and managers responsible for their implementation?
- Where are HACCP plan records maintained? Are they available for review by appropriately authorized personnel?
- Are all records pertaining to the control of CCPs available? Where and how long are they kept? Who is responsible for maintaining these records?
- Is the effectiveness of HACCP plan(s) verified by additional tests? Who is responsible for deciding what additional tests are appropriate and who reviews the results of such tests?
- Does the plant manager and his/her staff understand the HACCP concept and provide proper support for its adoption and maintenance? Who is responsible for HACCP training within the Plant? How effective is this training?
- On the basis of the review, have the HACCP plan(s) been properly established and implemented? Are there any recommendations for correction or improvement?

tion procedures. An example of a completed HACCP worksheet for the paella process illustrated in Figure 58–3 is shown in Exhibit 58–5.

Documentation Necessary for the Implementation of the HACCP Plan. This includes procedures and work instructions for operational activities, monitoring activities, corrective actions to be carried out at each CCP, and procedures for verification.

Records Obtained During the Operation of the HACCP System (Operation, Monitoring, Corrective Actions, Verification). The documentation system should be appropriately managed. The ISO 9004 Standard[37] provides appropriate guidelines. For the system to be effectively managed, documentation, as the system itself, needs be only as comprehensive as necessary and commensurate to the risk involved.

58.5 APPLICATION OF QUALITY SYSTEMS

A quality system is the organizational structure for responsibilities, procedures, processes, and resources needed to implement quality management.[33–37] It is designed primarily to meet the internal needs of a company for an organizational framework to coordinate all activities concerned with the implementation and management of quality. See Figure 58–5 for an outline of the main elements and functions of a quality system.

Managers are responsible for:

- defining and formally expressing a company's quality policy (ie, the overall intentions and direction of a company with regard to quality, including safety)
- defining and documenting lines of responsibility and authority
- establishing the organizational structure
- allocating appropriate and sufficient resources
- providing regular review and assessment of performance against the quality policy.

Within the quality system, quality management and quality policy are implemented by quality planning (ie, the establishment of the quality objectives to be met for key elements of quality). This includes:

- safety, performance, stability, fitness for use, and the related requirements for quality (taking account of the stated and implied needs of the product users and all legal and other requirements of the society in which the company operates)
- quality control, which covers the operational techniques and activities that are needed to fulfill requirements for quality
- quality assurance, including all the planned and systematic activities necessary to provide adequate confidence that the requirements for quality are being fulfilled
- quality improvement, covering the actions taken to increase the effectiveness and efficiency of activities and processes to provide added benefits to both the organization and its customers.

In addition, all the elements, requirements, and procedures adopted by a company for its quality management system should be documented in a systematic and orderly manner in the form of a quality manual, quality plans, and quality records. The quality system applies to and interacts with all activities pertaining to the quality of a product and process and involves all phases from initial identification to final satisfaction of requirements and customer expectations. The system functions in such a manner as to provide proper confidence that all factors affecting the quality of products are under control, such control being primarily oriented toward prevention of quality deficiencies. It is also a management resource in the optimization and control of quality in relation to risk, cost, and benefit considerations.[33–37]

The ISO 9000 series of standards[33–37] is an attempt to rationalize and harmonize the diverse approaches in this area. Two types of standards are presented in this series. The first, ISO 9004,[37] provides guidelines for the development and implementation of an inhouse quality system and is designed primarily to satisfy the internal managerial need of a company for enhanced productivity, cost-effectiveness, and confidence in regard to fulfilling customers' expectations. The second is ISO 9001, ISO 9002, and ISO 9003,[34–36] which provide models of reference to be used in contractual situations. They identify the elements the quality system of the supplier or producer should cover as a minimum and serve as criteria for the formal assessment, recognition, and accreditation of the quality system, usually by a third party. Such models differ according to the functional activities to be developed by the supplier or producer to ensure that the requirements of the contract are being fulfilled: ISO 9001, when the activities may involve design, development, production, installation, and servicing; ISO 9002, when the activities cover production and servicing; ISO 9003, when the conformity with the specified requirements is to be ensured through final inspection and tests only.

Developing the requirements of the ISO standards goes far beyond the scope of this chapter, which considers the development of quality systems in relation to food safety and HACCP. A company accredited to an ISO 9000 standard has had to consider each paragraph of the standard and to fulfill its specified requirements; however, when dealing with such a company, one should be aware of the positive and negative aspects of ISO 9000 accreditation. The first relates to the fact that such standards delineate only a generic framework for an organizational approach. They do not identify the methods by which the identified activities should be carried out. This is beneficial in avoiding an excess of formalism with regard to accreditation, while allowing for flexibility to adapt to the practices of each industrial sector. It means that the management of a company has the responsibility for choosing the most appropriate and efficient method to be used with specific regard to the activity, the product, the process, and the quality attribute under consideration. The second refers to the choice of the standard. ISO 9003, limited to final inspection and testing, usually is considered as inappropriate to the food processing industry because of the limitation of end-product sampling and testing to provide appropriate confidence in products meeting their requirements for quality. ISO 9002, which covers production and servicing, generally is considered the most appropriate standard for the food manufacturing sector; however, a specific difficulty may arise from the choice of ISO 9002. Basically,

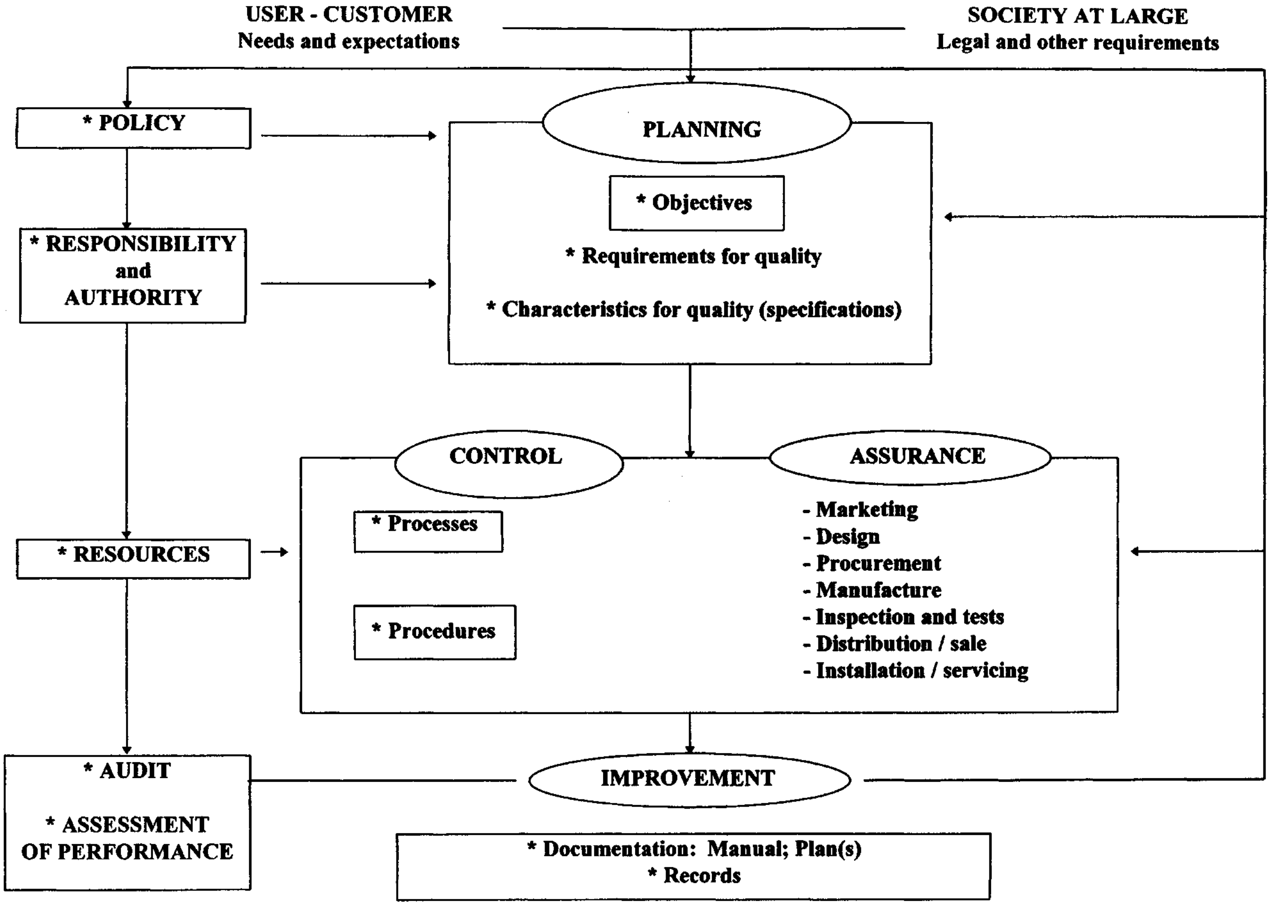

Figure 58–5 Fundamental Elements and Functions of a Quality System

this standard is to be used when the requirements for the product are expressed in the form of established or specified characteristics or specifications and when an appropriate confidence in the product meeting the stated requirements can be obtained by the demonstration of the manufacturer's ability during production.[35] This clearly means that the output will reflect only the requirements that have been stated. A possible consequence is that if such requirements have some deficiencies, or if they do not reflect all consumers' expectations, the product manufactured to such requirements will be deficient or will not fully meet consumers' expectations. Such considerations are crucial where safety is concerned. Safety starts at the product/process concept and design stages, and specifically requires proper hazard analysis and management decisions. The question, therefore, is how to introduce such considerations into a quality system, while identifying the most appropriate methods to do so.

The answer is simple: deal with safety matters by preparing a specific safety assurance plan based by priority on HACCP concepts and methodology. The concept of a "quality assurance plan" on which this approach is based refers to "a document setting out the specific quality practices, resources, and sequence of activities relevant to a particular product, contract or project" (ISO 8402). A quality assurance plan is an important tool. It identifies key elements in the product necessary to provide fitness for use and means by which they are provided and measured. With regard to such key elements, a quality assurance plan operating within the quality system is particularly useful in the following situations:

- where design (or redesign) is necessary or may be complex
- where all aspects of product/process design have not been fully assessed and validated
- where production is complex due to several factors such as availability of validated processes, number and diversity of operations, and high impact on product characteristics critical in regard to its performance.

The management of safety is a critical and complex issue in the food industry, which fits very well in the scope and field of application of a specific quality assurance plan. It is also where the use of HACCP as an effective tool has priority. An HACCP-based safety assurance plan specifically applies to a particular product and its process of production and assesses the activities specifically related to safety hazards. In contractual or regulatory situations, such a plan can be used to demonstrate that safety matters have been properly addressed and that appropriate control is being carried out. From a practical point of view, two situations are possible for the implementation of an HACCP plan.

The first occurs where no formal quality system exists. Here the HACCP approach assists in addressing many of the elements of the ISO standards with specific regard to safety.[38] When subsequently introducing an ISO 9000–based quality system, the safety assurance plan based on HACCP becomes a basic constituent of the quality system; in fact, a company following the 12 steps in applying HACCP will find itself well down the road to complying with ISO 9000 requirements.

The second occurs where there is a formal quality system in place. Here, the HACCP plan defines the specific application of the quality system to product safety. It may contain specific requirements with regard to safety that are more stringent than required by the overall quality system (eg, design validation in an ISO 9002 context) and otherwise refer to the elements of the quality system that are relevant to the product safety. In both cases, the safety assurance plan based on HACCP and the quality system are intimately associated and their integrated use provides additional benefits.[44]

In particular, the quality system facilitates the management of safety and use of HACCP in three ways. The first is that appropriate control of several activities can be established through the GMP (eg, sanitation, preventive maintenance, training of personnel), thus allowing the specific safety assurance (HACCP) plan to focus on specific and critical aspects in regard to safety (and, where appropriate "keepability"). The second is that the quality system addresses some elements that are not explicit components of HACCP, although important for its effective management. These include management responsibility and policy (provisions for safety and HACCP), quality system organization (establishment of a specific safety assurance plan), contract review, document control, product identification and traceability, internal quality audits, and training. The third is that ISO standards (ISO 9004 in particular)[37] provide organizational guidance to appropriately carry out specific activities that are components of HACCP. These would include design control (validation of product and process design with respect to safety), process control (specific process characteristics and CCPs), control of nonconforming products, corrective actions, and quality records.

Conversely, HACCP provides assurance that safety matters have been addressed properly and that appropriate control is established at all relevant stages of the product cycle (ie, design, purchasing, production, inspection and testing, handling, storage, delivery, servicing). Integration of GMP, HACCP, and a quality system such as ISO 9000 will deliver benefits to the food producer by providing greater certainty that foods marketed will be safe, and to the consumer that foods purchased will not be harmful to health.

58.6 CONCLUDING REMARKS

The consumer expects to receive foods that, as well as meeting expectations of quality, are safe. Meeting safety expectations is a core business aim, and meeting food safety requirements is part of the price of admission of a company's products to the marketplace.

Technical support is essential to the production, processing, packaging, and distribution of microbiologically safe foods. Underpinning research is of paramount importance to achieving such technical aims, and the chapters in this book and elsewhere[30,40] highlight microbiological research needs to further develop high-quality and safe foods. The use of properly formulated guides to good manufacturing and hygiene is a practical means of disseminating this knowledge to all food producers. Their development by food manufacturers and their trade associations should be continually encouraged by governmental agencies.

The modern approach to identifying microbiological safety requirements for a foodstuff is ideally based on a two-stage procedure (ie, the process of government-led risk analysis [risk assessment, risk management, and risk communication]) followed by the use of HACCP by industry to identify and manage the specific microbiological hazards associated with a particular food production operation. However, microbiological risk assessment is in its infancy, and we have much to learn before we can make scientifically-based quantitative assessments of microbiological risk; see Chapter 65.

The further development of HACCP requires more reliable means of identifying hazards and developing sound rules for establishing CCPs and critical limits; this may well be assisted by the further development of microbiological databases and predictive models of microbial growth, survival, and infectivity.

The development of risk analysis and HACCP will require scientists in academia, government, and industry working together closely. It is important to recognize the links between government and food industry activities in food safety assurance; such links are illustrated in Figure 58–6 and show the important interactions arising from these activities.

If the benefits of HACCP are to be applied most widely, and to benefit all food producers and consumers, it is important that the system be kept flexible in its application. It must be seen clearly as a tool for use by industry and not as a means of enforcing unnecessary controls on industry. The authorities' role should be one of encouragement and assistance in applying HACCP.

The food industry must organize itself to provide greater assurance that the procedures that are necessary to ensure microbiological safety are properly managed. It is essential that quality management systems are more widely used throughout the food industry and that these incorporate proper consideration of safety needs by the use of HACCP within the framework of a quality management system,

such as ISO 9000. The increasing sophistication of many modern food production processes, and the greater use of milder conditions for processing foods, requires far greater control to be exercised over production procedures. Only companies that recognize what controls and operational practices need to be in place to market safe foods are likely to be successful in the marketplace in the 21st century.

59.1 INTRODUCTION

Problems caused by excessive microbial contamination of foods tend to be expensive, particularly if they result in public recalls. As a result of the development and application of increasingly mild preservation technologies, such as ohmic heating, microwave heating, and the use of modified atmospheres and chilled storage (see Chapter 3), processed foods become more sensitive to microbial (re)contamination, requiring greater control of the manufacturing process.

The hygienic design of food factories and equipment plays an important role in controlling the microbiological safety and quality of the products made. This is officially recognized in legislation, such as the various directives of the European Commission (eg, the "Hygiene of Foodstuffs" directive[16] and the so-called "Machinery" directive),[15] which incorporates an annex relating to "Machinery for Agri-foodstuffs" and in the United States (US) (eg, the "Pasteurized Milk Ordinance"[24] and the Fish and Fishery Products Hazards and Control Guide).[25] The Codex Alimentarius[13] also addresses hygienic design in relation to food safety.

A hygienic factory should prevent products from:

- having too high microbial counts
- containing toxins of microbial origin
- containing residues of chemicals used for cleaning and disinfection
- being contaminated with other nonfood substances such as lubricants, coolants, and antimicrobial barrier fluids
- containing foreign bodies, such as pieces of metal, plastic, packing material, and insects (or other vermin) or parts thereof.

Acknowledgments. This chapter could not have been written had I not had many fruitful discussions with Unilever colleagues, all of whom have significantly contributed to the state of the art in the design of hygienic food factories. In particular I would like to mention Tineke Mostert, Roy Curiel, Harry van Eijk, Tony Hasting, Bob Maller, Frans Majoor, Sebo Poel, and Don Smid. In this respect I should also mention the members of the Main Group of the European Hygienic Equipment Design Group and the 3-A Steering Committee in the US. I am very grateful to the editors as well as to Tineke Mostert and Roy Curiel for their painstaking reading of the various drafts of the manuscript and their very helpful and welcome comments and suggestions.

High Microbial Counts. Too-high microbial counts may be the result of high counts in the raw materials or the survival of microorganisms due to failing of process control or equipment; too-high counts also may be caused by recontamination of product. A process also may fail because of inefficient mixing or too-short treatment times. Inefficient mixing may cause inhomogeneous temperature distribution, and the measured temperature may be different from the temperature of the bulk of the product and—most importantly—from the temperature of the coldest part of the product. Too-low temperatures in thermally processed food also may be the result of build-up of food or food-derived materials on heat-exchanging surfaces. A wrong design of the factory may result in mixing raw with decontaminated product or the transfer by other means (eg, air, personnel, or equipment) of microorganisms from raw to finished product ("cross contamination"). Equipment, correctly cleaned and sanitized before use, may be recontaminated by the product as a result of an incorrect startup procedure; the contaminated equipment may subsequently recontaminate passing product. Further, individual components of process lines, if of incorrect design, may cause recontamination. Incorrectly designed process lines, even if properly cleaned (eg, manually with disassembly where needed), may lead to contamination of product and thus to high microbial counts because microorganisms may multiply to high numbers in areas where product is stagnant ("dead" areas) and may release large numbers to passing product. Such areas often are found at the sides of conveyor belts and in pipelines, where appendages such as pressure gauges and temperature sensors have been mounted. A stagnant area that seems unavoidable is the rim of the filling nozzle, where there is always accumulation of product. A single microorganism may convert the accumulated product into a reservoir of spoilage or food poisoning microorganisms. The contaminated product will continually re-enter the product being filled, sometimes as small lumps or droplets, depending on product viscosity. The process equipment itself may still be contaminated after cleaning and sanitation as a result of not being cleanable (due to the presence of non-cleanable features such as screw threads and crevices), not being given the required treatment (because it is not resistant to the heat or bicidal chemicals), or just of not being properly cleaned because the cleaning procedure is incorrect or the control system does not function or has not been set up properly.

In an open plant, where product is exposed to the environment, microbial contamination may come from the air, dust, condensate falling down from chilled pipelines, splashes of other liquids, insects (or sometimes even birds), and directly from people touching the product. The risk of contamination is inversely proportional to the cleanliness of the plant and hence to its cleanability, which in turn depends on the design of the building and design and installation of all that is inside the building.

In closed process lines, the incorrect use of so-called "mixproof" valves may lead to recontamination. Fouling of the holding section in a continuous pasteurizer or sterilizer may significantly reduce the volume in that section, leading to a too-short residence time. If seals between components fail, product may leak to the outside of the line. Microorganisms may then multiply in the product and grow back to the product side. In the case of dynamic seals, such as those for shafts of valves, pumps, and mixers, the movements of the shaft will assist the transfer of product to the outside and of microorganisms to the product side. This applies to reciprocating shafts and to a lesser extent to rotating shafts, the latter always displaying some axial movement. Where it is necessary to prevent the ingress of live microorganisms, double seals with microbicidal barrier liquids are used. Such barriers, however, if not timely replaced, may become a growth medium for microorganisms.

Where microbial growth in the product is controlled by its composition, failing sensors or incorrectly calibrated measurement equipment may result in deviations in pH, water activity, and concentration of preserving agents.

The primary packaging material may be contaminated unacceptably, because the quality as delivered is not good enough or—in case of aseptic packaging—because of inadequate decontamination or of recontamination of the material.

Toxins of Microbial Origin. Microorganisms may produce toxins that survive heat, such as *Staphylococcus aureus* enterotoxin and many mycotoxins, such as aflatoxins, ochratoxins, trichothecens, fumonisins, and zearalenones. Cooking, pasteurization, and sterilization do not destroy such toxins; therefore, if a product—at any stage in the product chain—has acquired a too-high count of toxigenic microorganisms, that product should never be upgraded by destruction of the microorganisms, but should be destroyed to avoid it from being used.

Chemical Residues. Chemicals used for cleaning and disinfection of equipment or packing material should never be left behind to contaminate the product. The concentration of any residues should not exceed the legally accepted level. For instance, in many countries the product may not contain more than 0.5 mg hydrogen peroxide per kg product. Preferably, residues should be nontoxic. Intrinsically toxic products such as tetraborate and chloroisocyanuric acids should be avoided in food processing plants.

Construction materials (ie, metals, polymers, elastomers, but also auxillary substances such as lubricants, antimicrobial barrier liquids, coolants, and signal transfer fluids) may contain toxic substances that may migrate to the product, depending on product characteristics (such as pH and chloride contents). Therefore, materials used for the construction of components that may come in contact with food should be selected very carefully. Under the conditions of use, these materials should not be able to make a food product toxic.

Foreign Bodies. Foreign bodies may originate from raw materials (bones, insects) and packing material (wood, cardboard, metal, glass, polymers), but also from the building (glass, wood, chalk, paint flakes, screws, nails), equipment (bolts and nuts, security rings, pieces of gaskets, metal and polymer shavings), the environment (insects, rodent and bird droppings, dust), and people (jewels, pen, pencils, hair, hairpins, buttons, nails) and their activities (tools, bristles from brushes, pieces of cloth). The design of the plant should prevent foreign bodies from contaminating the product in all stages of the manufacturing process. The correct choice of construction materials; measures to prevent the presence of insects, rodents, and birds; and facilities for personnel to safely store their belongings and their tools will greatly reduce the risk of foreign body incidents.

Hygienic Design. A factory that has been designed with hygienic requirements in mind, process lines correctly built from hygienic equipment, and properly operated and maintained will produce food products that are safe and of excellent microbiological quality.

This chapter deals with the influence of the design of a plant on the quality and safety of the product and discusses hygienic requirements. Many pitfalls will be discussed, as will ways to avoid them. Examples of wrong designs and of designs complying with hygienic requirements will be given. Examples are just that; there may be other solutions, particularly because of the rapid developments in new construction materials and methods, for buildings as well as equipment.

A final remark: there are many types of food, and susceptibility to microbial attack varies widely. The only way to decide on which measures are needed is to carefully estimate the risk for each product and every single process step (ie, apply Hazard Analysis Critical Control Point) (see Chapter 58).

59.2 FACTORY DESIGN

59.2.1 Layout of Food Factories

The production plant must be built in such a way that finished product cannot be recontaminated by raw materials (including packaging materials) or any intermediate product. Thus, the flow of material should be from the raw materials reception to the separate finished product exit. Similarly, it should not be possible for personnel working with raw materials to move to or pass through upstream areas, where products may become contaminated. Stores should be located and provided with entrances and exits in such a way that to obtain clean materials, no less clean areas need to be crossed. Functions not directly involved in the manufacturing process, such as administrative offices, laboratories, and canteens, should be separated from the product areas to prevent staff from entering these areas. Preferably, they should be in a separate building. If not, they should be separated from the product areas by a corridor.

Figure 59–1 gives a generalized example of the layout of a food factory, assuming that there is a process step following the steps where the relevant microorganisms are inactivated, and not followed by another process step that would provide the required inactivation. Arrows indicate the (compulsory) direction of the flow of materials. Which areas are needed should follow from a hazard analysis, taking into account product vulnerability and shelf life requirements.

Reception and Storage Areas. The layout of the factory must be such that raw materials can be properly stored in the correct areas immediately on reception. Products presenting different hazards or with different vulnerabilities should not be stored together, nor should it be necessary to cross different storage areas. In the current example, dry, frozen, and chilled raw material areas all can be reached from the unloading bay. Also, the packing materials, chemicals, and spare part stores can be reached from that bay. Although liquid raw materials may be delivered in containers like barrels, drums, bottles, cans, or jerrycans, often they are delivered by tank

cars (road tankers), which is the case in the example where the liquid raw material reception is at a separate area, close to where the liquid is to be processed. The outlet valve of the road tanker is connected to the inlet valve of the reception area, which is mounted on the outside wall. The connection is cleaned and sanitized before the valves are opened to transfer the contents of the tank to the reception vessels inside. The product often is pasteurized or sterilized immediately on reception. It may be necessary, however, to keep the product cool for some time before heat treatment.

The relatively large quantities of cleaning and sanitation chemicals are delivered directly to the store next to the cleaning station. This station may host both the cleaning-in-place (CIP) installation and facilities for cleaning-out-of-place (COP), such as an industrial washing machine.

There can be many sources of water, such as municipal water, surface water, and well water. Whatever the source, often the quality needs upgrading, and a water treatment facility is common.[12] For convenience, the treatment plant is located close to where the water is needed most.

Processing and Packaging Areas. To prevent excess contamination before delivery to processing and primary packing areas, the outer packing materials must be removed in a separate space, which should have adequate facilities for dust-free disposal (eg, a well-vented compactor). Means for transporting raw materials to the processing and packing areas should stay in those areas.

In the example, after primary processing (which can be all kinds of processes, including cutting, shaping, dough preparation, mincing, sorting, and assembling), the product is passed to the cooking area. The cooked product must be protected against recontamination and, therefore, is transported by suitable means (often a conveyor belt or chain) to the high-care area, through a properly dimensioned slot in the separation wall. In the high care area, the final product is prepared, requiring the addition of the pasteurized liquid component (which could be a dairy-based product). From the high-care area, the product goes to the primary packing area, where the product receives its protection against recontamination. To reduce the risk of contamination while the product is not yet packed, the high-care area and the primary packing area are kept at a pressure above that in the adjacent areas.

From the primary packing area, the product is transferred to the secondary packaging and palletizing area and from there to the finished product store.

Workshop and Other Nonproduct Areas. To prevent undue risks of contamination, the workshop must have no direct access from any process area. There are connections only to the equipment and spare parts store and to the outside.

Administration, management offices, meeting room, library, change rooms, rest rooms, kitchen, and canteen are all separated from the production areas. The laboratory too should be separate, as in the example. That way laboratory staff can access all areas where product may have to be sampled (ie, all raw material stores and all production and packaging areas) without having to cross other areas.

Personnel can enter product areas only via disinfecting floor mats and a facility to wash, disinfect, and dry their hands. The high-care and the primary packing area can be accessed only via an area designed to reduce the risk of contamination of product in those areas. There is a step over, where only special footwear is allowed.

59.2.2 Outside Areas

Factory Surroundings. Preferably, food factories should not be located near areas where levels of microorganisms, insects, or rodents can be exceptionally high. Examples are farms, wastewater treatment plants, and municipal waste disposal areas. Nearby water (lakes, rivers, marshes, canals), although often desirable for other reasons (eg, transport, own water supply), is also highly undesirable from a hygiene point of view. This applies particularly to stagnant water. If the factory happens to be in the vicinity of such an area, extra measures may be required to achieve the hygienic conditions needed to produce safe food. Such measures may include fitting double external doors and the installation of additional air filtration plant.

The immediate environment of the factory should discourage pests entering or breeding. The environment therefore should be kept dry. If possible, the factory should be at an elevated level so that the soil outside will slope downward. Trees, shrubs, and flowers all attract insects and other animals and thus should be avoided in the immediate environment of the factory. Local specialists (biologists, entomologists) should be consulted about the effective distance between plant growth and the factory to prevent problems.

Often factories are illuminated at night. If this is the case, care should be taken that no insects are attracted. If possible, insect-attracting lights (high-UV lamps, mercury vapor lamps) should be positioned away from the building and lighting that is less attracting (using low-ultraviolet [UV] lamps, sodium vapor lamps) should be used if needed close to the factory building. Contrary to commercial claims, there is no evidence that ultrasound repels insects.

To keep pets and other animals away, it is recommended to install a fence around the factory. To be effective, the fence must be high enough and not of a design that serves as stairs or steps for animals. The fence must also extend deep enough into the soil to stop burrowing animals. The fence should be uninterrupted and any gate should be automatically closing.

Building Exterior. To deny birds places to breed, the outer walls of the factory should not have ridges or other protrusions. Where protrusions are unavoidable, measures must be taken to discourage birds from settling. The lower part of the wall should be rodent tight and the construction materials must be rodent proof. Rodents must also not be able to gain access to the inside by digging. The contractor should be required to guarantee that the building will be rodent proof. This applies particularly to the connection between the foundation and the external wall. Roofs, too, should be such that they do not attract vermin. The roof should therefore be kept dry and thus slope (>1%).

Air inlets must not be located near air outlets. The openings must be provided with screens to prevent insects and other pests from entering.

There should be no access for birds or insects to the space between the roof and a suspended "false" ceiling. Roofs and walls should be easily cleanable.

Doors and Windows. Doors and windows, if left open, allow the entrance of pests; therefore, doors should be self-closing. Doors and windows that are opened only rarely (eg, those for emergencies only) provide ideal places for insects to breed; therefore, care should be taken that doors and windows fit tightly, reducing any crevices between the door or window and its frame to a minimum. Depending on local conditions, it may be advisable to fit doors and windows with flexible strips; thresholds may be used. Where thresholds are not acceptable, other means should be used to seal between the floor and the door. There should be a program for regular inspection and cleaning of doors and windows. To avoid the attraction of birds, there should be no external window sills. If unavoidable, the windows should slope steeply without creating a breeding place for insects on the underside. Doors and frames should be made from (or treated with) rodent-resistant materials such as stainless steel. In areas where strong winds are common, doors should be located on the downwind side of the building. If windows are needed to provide daylight in the work area, glass bricks should be considered. They can be mounted flush with the wall and be maintained very easily.

59.2.3 Indoor Areas

To avoid cross contamination of products, the position of any air inlets and outlets should be carefully chosen. The air should move from the cleanest side or sides (where the finished products are) to the least (microbially) clean sides (where the raw materials are). This should be done correctly, which means for instance that the location of doors and windows should be taken into account. In some cases, doors must be interlocked so only one of them can be open at a time. To ensure that safety exits are not used as normal doors, they may have to be provided with alarms or be locked with a special key, which is kept behind a glass panel to be broken in case of emergencies.

All surfaces must be cleanable, which must be taken into account when selecting construction materials, and must be able to withstand the chosen cleaning methods, temperatures, and chemicals. Cleaning methods required usually are determined by the type of soil (including product residues) to be removed. Walls may have to be resistant to high-pressure jet cleaning and floors to mechanical cleaning with brushes; all surfaces may have to be resistant to chlorides and hypochlorite, hot alkali, and hot acid solutions. Decisions on cleaning methods should be made before, or in conjunction with, deciding on construction materials.

Floors. Floors must be smooth to ensure cleanability, they must not be slippery and they must be strong enough to withstand heavy duties such as the movement of forklift trucks. As far as known, there are no materials that meet all of these requirements completely, and the choice therefore usually will be a compromise.

Smooth concrete floors are normally fully acceptable for reception and raw material storage areas. In areas where product is not protected, ceramic tiles or resin floors are preferred. In high-care areas, seamless resin floors are the best choice.

If ceramic tiles are selected as flooring material, the supporting structure must be strong enough not to bend too much under the maximum possible load; otherwise, the tiles or grouting may crack and eventually the tiles may loosen. Loosening may be accelerated if the floor is moist; the presence of nutrients allows microorganisms to grow between and underneath the tiles, producing acid and dissolving the grouting.

If a resin is chosen as seamless flooring material, it must be certain that the resin can withstand all necessary and accidental treatments possible. This requires the material to be resistant to both cold and hot water, greases, cleaning and sanitizing agents, and to the spot pressure (pressure per unit area) caused by heavy machinery. The materials also must withstand abrasion caused by moving equipment such as trolleys. Resin floors should not be used in places of frequent use of forklift trucks.

Several types of resins (epoxy, metacrylate, polyester, or polyurethane) are available, and the selection must be based on the duty of the floor. The supplier should be able to guarantee the required chemical and wear resistance and the maximum spot load.

Any floor likely to become wet must have rounded corners where the floor meets the wall. If tiles are used, special tiles are available (Figure 59–2).

With the exception of areas that will always be dry, floors should slope toward drains or gutters. A slope of approximately 2% is an acceptable compro-

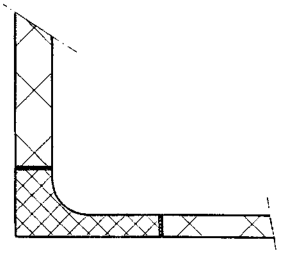

Figure 59–2 Tiles Avoiding Uncleanable Sharp Corners. Courtesy of Unilever Research Vlaardingen.

mise between the need for draining and the usual functions of a floor. In permanently wet areas, it will be hard to prevent eventual penetration of moisture, which will accumulate between the top floor and, in most cases, the concrete support floor. To protect chemical attack of the support floor, an impermeable bitumen layer (membrane) should be installed on top of the support floor.

Some flooring materials may be less slippery in combination with special footwear. The supplier should be able to advise and give guarantees.

Walls. Walls should be smooth and cleanable. They may be made from a variety of materials, such as concrete, bricks, or panels. Bricks and concrete should be covered by ceramic tiles or a good quality coating or paint. The choice of coating requires specialist advice as there are many coatings with widely varying chemical and thermal resistances, even within a type of coating, eg, epoxy, urethane, etc. The coating must be firmly fixed and sealed to prevent ingress of moisture. If tiles are chosen, they must be properly grouted to ensure they do not come loose during normal use, including cleaning. Expert advice (and guarantees) should be sought from specialist companies. Panels may be made from plastics, glass, aluminum, or stainless steel and often are sandwiched. In the case of sandwich panels, it must be ascertained that all sides comply with the chemical resistance required. Wooden panels should not be used in areas that may become wet. In dry areas they may be acceptable, provided the finishing is of good quality and the wood has been treated against the proliferation of insects and the areas are effectively kept free from rodents. It is important that all seams are reliably sealed. In some cases, seams can be sealed by welding with the parent material. In other cases, and where walls meet the floor, sealants should be used. The supplier should guarantee that the sealant gives a strong impervious bond and thus will not come loose from either the panel material or, where relevant, the flooring material.

Grouting. Normal cement grouting is hydrophilic and will absorb moisture and nutritious spillages, the presence of which may lead to microbial growth. Microorganisms often produce acids that may attack the grouting; therefore, in areas that may become wet, cement mixed with synthetic resins should be used as sealant between tiles.

Ceilings. Dust will always accumulate on the upper side of ceilings. Drafts cause pressure differences, which will move the dust through seams and openings for service lines in the ceiling; therefore, ceilings should always be hermetically sealed. Panels similar to those used for walls may be used. Lighting preferably should be built into the ceiling, the underside flush with the ceiling. If it is necessary to have lighting fittings at lower level, the upper side should slope sufficiently to avoid the accumulation of dust. The same applies to any other suspended items, including exposed beams. Ceilings and anything suspended from them must be easy to clean.

Doors and Windows. Requirements basically are similar as for exterior doors and windows. If windows need to be open, they must be provided with insect-proof screens. As some insects, often occurring in large numbers, are as small as 0.2 mm, the screens should have openings smaller than that.

59.2.4 Additional Requirements for Reception Areas and Raw Materials Storage Areas

Reception Areas. The area in which products are received should be designed to make it impossible for any vehicles to pass directly into the area where raw materials (including packing materials) are stored. Noticeboards are not sufficient: a physical barrier is essential. Unloading bays are very effective. As the doors to such bays will be opened for a prolonged time, the design of the bay must prevent the entrance of rodents. This can be achieved by using only smooth, vertical walls at the outside (ie, no stairs outside). Access of personnel should be by stairs inside the building only, or from inside the vehicle. To prevent birds and flying insects from entering, there should be flexible curtains or an effective air screen.

If vehicles must enter a storage area, they should pass an area where they can be cleaned before entering.

To prevent raw materials from contamination with dust, dirt, and insects, the layout of the reception area must be such that unloading is possible without placing the materials outside on the floor.

It must be possible to transfer vulnerable product that needs to be chilled or must be kept frozen to the chill or freeze storage area immediately. This must be done without opening the entrance to those areas for a significantly long time. If large quantities need to be unloaded into such areas, bays should be constructed that allow the unloading opening of the vehicle to be connected to, or for a short length, the vehicle to enter the area. This should be done in such a way that the clearance between the vehicle and the entrance is sealed sufficiently to prevent an unacceptable rise in temperature anywhere in the chill or freeze storage area.

Whatever way the product is unloaded, it must be possible to identify and if needed to label the incoming material and to take samples as needed from any batch of raw material delivered.

Storage Areas. All parts of the storage areas should be designed so that insects and vermin cannot hide and survive and that all surfaces are accessible for cleaning and inspection. There should be no deep recesses: supports of chests, cabinets, and scaffolding should be sealed to the floor or wall. The same applies to any appendages, such as lighting and switchboxes. Unless it is expected that the storage area will remain dry, surfaces should be nonabsorbent.

To prevent damage to the products stored and to prevent their contamination, the areas and constructions where the products are stored should be free from sharp protrusions, such as unprotected ends of beams, nails, bolts, and screws.

There must be separate areas for the storage of packing material, chemicals, spare parts of machinery, and tools. Access to the chemicals store should be restricted. All containers should be provided with a warning that they should not be in any production area during the production, with the exception of chemicals intended for use during production, such as disinfectants, lubricants, glue, and ink (in which case the storage in the production area must be limited to the amount needed for a reasonable production period).

There must be separate stores for intermediate and finished products. Personnel handling raw materials should not have direct access to the processing areas or the finished product stores.

Ventilation and Air Conditioning. If materials are stored for relatively long times (several days or more), the growth of microorganisms, particularly molds, may become a serious problem if the humidity in the storage area is higher than 55%. It is therefore important to keep the humidity below that value. Depending on local conditions, ventilation may be sufficient. If, however, microbiologically susceptible materials, including cardboard, which is used abundantly as packing material, are stored for more than a few days and the humidity in the environment is high, it may be necessary to install air conditioning or dehumidification equipment. In some cases, it may suffice to use conditioned air from the production area. Alternatively or in addition, the temperature in the relevant storage area may be reduced.

59.2.5 Additional Requirements for Production and Packaging Areas

Production areas may be divided into areas where product is exposed, the so-called "open plant" and areas where product is enclosed, called "closed plant." In open plants there is a higher risk of contamination of product from the environment. During primary packaging, the product is exposed and thus the area where product is packed should be treated as open plant, even if the product is delivered from a closed process line. Many requirements apply to both open and closed plants.

General Requirements for Open and Closed Plants. Basic requirements are similar to those discussed under reception areas and storage areas. Production areas should be designed so that vehicles coming from outside the factory cannot enter. Instead, materials should be transferred to vehicles dedicated to indoor transport.

All surfaces in the production area must be cleanable. Insect-proof screens with a sufficiently fine mesh should be used where open windows are used. There must be no niches or recesses where insects can hide. Equipment must be sealed to the floor or wall or enough clearance must be left for inspection and cleaning. Surfaces should be nonabsorbent unless only dry products are produced and the production area will always be dry.

It is strongly recommended to take all measures needed to prevent ingress of insects into areas where product or primary packing material is exposed, so that there will be no need for insect light traps. If insect light traps (with either electrocuter or adhesive surface board) are used, it must be made certain that trapped insects cannot contaminate food. They must not be mounted over exposed product or exposed surfaces (of machinery or packing materials) intended for product contact. The traps must be cleaned frequently to prevent other vermin from feeding on the dead bodies. It must also be understood that UV lamps used in the light trap may break and cause contamination of product with glass. Some manufacturers supply shatterproof lamps.

Gutters and Drains. Where possible, gutters (channel drains) should be avoided and hygienic floor drains (Figure 59–3) should be used instead. The cover of the drain should be flush with the floor. To reduce the risk of blocking with solids, the openings

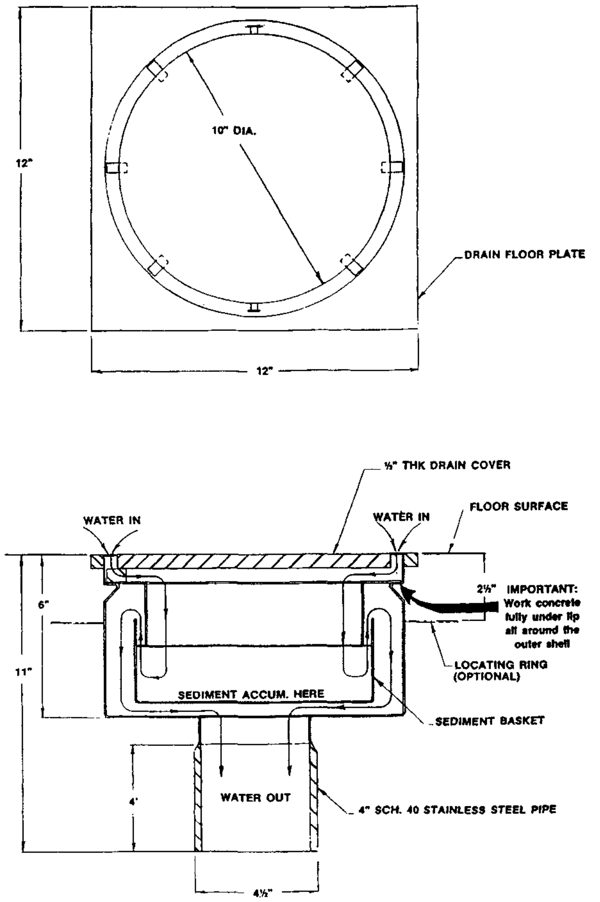

Figure 59–3 Example of a Hygienic Floor Drain. Courtesy of Kusel Equipment Co., Watertown, Wisconsin.

in the cover should preferably be tapered, the largest cross section at the underside. U-traps should be avoided as they accumulate dirt, providing a breeding place to insects. Floors should slope toward these drains. Floor drains must be cleanable. If they are placed in areas where the hygiene requirements are high, it may be useful to have drains that are suitable for the insertion of blocks or rings of disinfectant-releasing materials.

If gutters are necessary, they too should be designed to be easily cleanable. As they will not be covered all the time, they should be positioned near walls or other areas where there is no traffic.

Acoustic Absorption Materials. If the level of noise must be reduced by acoustic materials, care should be taken that these materials do not adversely affect the cleaning of the production area. Regrettably, sound absorption is best with porous materials, which cannot be cleaned. Moreover, for best effect they must be mounted some distance from walls or ceilings, creating places for nests of insects and other vermin, that are difficult to inspect and clean. Therefore, materials for hygienic applications have been developed that are somewhat less effective, but smooth and cleanable (by foam or mist). They can be mounted directly on the wall (Figure 59–4) or be suspended from the ceiling (Figure 59–5). In the latter case, cleaning may be more difficult and require (mobile) scaffolding or trucks with lifts.

Ventilation and Air Conditioning. Whether product is exposed or not, the risk of contamination from the environment will always be proportional to the concentration of microorganisms in that environment. It is therefore important that multiplication of microorganisms in the production area is prevented. As microbial growth is possible only in the presence of enough moisture, such growth can be prevented by ensuring a sufficiently low humidity. As molds will grow at water activities down to approximately 0.6, keeping the relative humidity at or below 50% is highly recommended. A humidity of 50% is also comfortable for human beings. Depending on the local environmental humidity, the installation of an air conditioning system may be required to keep the humidity down to 50%.

Water vapor may condense on cold surfaces, causing too-high water activities locally. Therefore, water vapor should be properly vented near to where it is generated and the installation of hoods may be needed. This may be the case where product is cooked, where vegetables are blanched, or where equipment or utensils are cleaned and sanitized using hot solutions or steam. The inside of such a hood should be inspected regularly for cleanliness as there

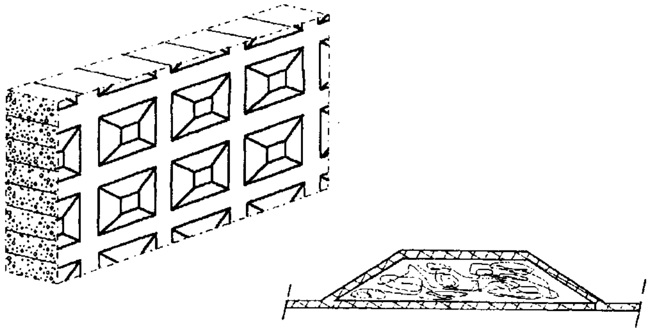

Figure 59–4 Sound Absorbing Panels with a Smooth Surface. Courtesy of Unilever Research Vlaardingen.

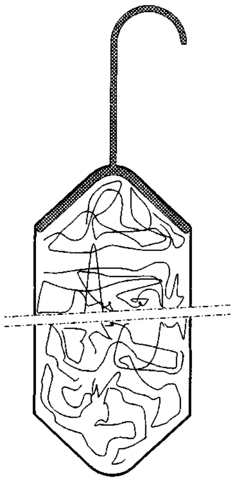

Figure 59–5 Smooth Acoustic Slabs for Hanging from the Ceiling. Courtesy of Unilever Research Vlaardingen.

the humidity will probably be high. It is likely that at least a part of the surface is at a temperature suitable for microbial growth, for at least part of the time.

Where dust is generated (eg, handling of dry powders, spices), care must be taken that the dust is extracted at that spot. For emptying bags, small or big, dust-free emptying systems are available, combined with dust-free packing material compactors.

Depending on local conditions, in particular the location of the factory (see Section 59.2.1), the microbiological product requirements, and the preservation processes used, it may be necessary to install air filters. See Section 59.3.3.

Dry Floors. Pools of water are ideal places for microorganisms to grow, in particular in food factories where the likelihood that sufficient nutrients are present is very high. The presence of pools of water and wet floors will also make it difficult to keep the humidity low. It therefore is strongly recommended to implement where possible a dry-floor policy (ie, a policy to keep floors dry at all times or, if wetting cannot always be avoided, to ensure that any moisture is removed as soon as possible). To achieve this, equipment should not be drained on the floor but into pipelines or gutters and there should be no hoses lying on the floor and spilling water, to be used in case product spillages must be chased away. Spillages should be collected and put aside in containers after which the floor is cleaned and dried. Water hoses should have self-closing nozzles and must be stored properly when not in use.

Thermal Insulation. If the outside temperature is low, even at a relative humidity below 50%, water may condense on cold surfaces, such as walls, doors, windows, and ceilings. If this is the case, the correct remedy is thermal insulation, preferably outside. If that is not possible and hence the insulation must be put on the inside, it must be made sure that it is completely isolated from the product area (eg, behind smooth and well-sealed panels, see Section 59.2.3).

Personal Hygiene. Hand-washing facilities should be installed near the entrance to the production area so that everybody entering the area passes these facilities. The taps should be operated without using hands (eg, by foot or elbow). Alternatively, electronic detection systems may be used. The facilities should include a provision of single-use (eg, paper) towels and cleanable waste bins. Rooms for changing clothing and footwear also should have adequate facilities for cleaning of hands and should provide locking facilities for personal belongings. Rest rooms (washrooms, toilets, flush lavatories) should be easy to clean and be provided with adequate means for cleaning, disinfection, and drying of hands. Preferably, operation of taps, dispensers, dryers, and doors should be automatic to minimize contamination risk.

In any area where direct or indirect contact with food is possible, nobody should be allowed access without a number of precautions aimed at avoiding product contamination risks. There are essential rules to prevent foreign body contamination:

- jewelry (including earrings and watches) should not be worn; they must be stored outside the production area in the lockers provided
- hair nets (also for facial hair) or effective caps or hats must be worn
- spectacles are allowed but must be tied to a necklace-string; preferably, the lenses should be made from nonglass material
- smoking and carrying cigarettes or any other smoking materials are not allowed
- eating, drinking, and carrying food, including sweets and snacks, are not allowed
- outdoor garments are not allowed and should be changed for clothing without buttons on the outside; continuous-thread polyamide zip-fasteners are preferred.

Other measures are aimed at preventing contamination with microorganisms:

- hands must be washed and, where product must be handled manually, disinfected on entry of any exposed product area
- hands also must be washed when leaving any rest room; having done so, it is still required to wash hands again on entering a process area, even if it means washing twice in a very short time
- shoes must be exchanged for shoes used only in the exposed product area; depending on the results of hazard analysis, it may be necessary to disinfect footwear on entering the food handling area
- factory clothing should not be taken home for cleaning, but left at the factory for professional cleaning at sufficiently high temperature to ensure inactivation of relevant microorganisms
- personnel must never move from less clean areas to cleaner areas without washing hands and changing factory clothing
- personnel with a health problem of microbial origin (or in case of doubt whether this is the case) should report to the company medical staff. When there is a risk of contamination of product, working in any exposed product or packing material area should not be allowed until free from infection.

Only production personnel and their responsible supervisors should have access to the food processing area. If technical staff, such as fitters, and professional visitors, such as food inspectors, must be given access, they should comply with all rules that apply to the area visited.

Packaging. During packaging, the product and often the product side of the packing material are exposed to the environment. The time of exposure, the concentration of microorganisms in the air, and the sedimentation rate of the microorganisms will determine the degree of infection of the product.

Even if packing is done aseptically, the rate of contamination of the packed product is influenced by the concentration of microorganisms in the surrounding of the packing machine. Depending on the acceptable contamination rate, the concentration of microorganisms in the area of the aseptic packing operation may have to be reduced.

59.2.6 High Care Areas

To keep contamination of exposed product under control, in addition to the measures that apply to all processing areas (see Section 59.2.5), extra measures may be required—which measures depend on the product and the intended storage, distribution, and shelf life. The measures may include restricted access, facilities to clean footwear, an area to change footwear and/or garments, maintenance of a positive pressure in the production area, and microfiltration of the air supplied to the area. A proper risk assessment should be carried out to establish which measures are needed to meet the targets set. Measures may include:

- a change area with a stepover that allows the exchange of footwear without contaminating the clean side with footwear from the other side
- supply of filtered air
- maintenance of a higher pressure to reduce ingress of contaminated air
- the use of gloves. Care should be taken that gloves are used properly. If not, they will increase rather than decrease the risk of product contamination. When using gloves to protect the product, no unclean surfaces should be touched. Gloves must be replaced frequently. As they promote the growth of microorganisms on the skin, care must be taken that these microorganisms cannot contaminate the food product; therefore, changing gloves should be done well away from the product (or primary packing material)
- mouth masks may be required; they usually are effective, provided they are replaced often enough
- if multiplication of microorganisms must be prevented during the processing in the high care area, which often is the case with meat products, the high care area should be chilled, typically to a temperature below 12° C. The actual temperature will depend on the possible rate of microbial growth in the product and the time the product resides in the area. Unless the residence time in the packaging areas is very short, these areas too must be cooled. Adequate clothing, which protects against the cold, must be provided. The clothing nevertheless must comply with the hygiene requirements listed above. For further information on hygiene requirements for high care areas, see the literature.[11]

59.3 EQUIPMENT DESIGN

The function of equipment is to convert raw materials into wholesome food products. If equipment is not designed correctly or assembled in the wrong

Next Page

way, the wholesomeness of the food may be impaired. Equipment may be the source of microbiological problems for a number of reasons. It may be that the equipment:

- cannot be cleaned and decontaminated and allows microbial growth, causing contamination of product in contact with the equipment
- should decontaminate (pasteurize or sterilize) the product but fails to do so
- although being cleanable, is such that part of the product resides in certain areas for too long a time, giving microorganisms time to multiply
- does not give the required protection against recontamination from the environment.

59.3.1 General Requirements

Materials of Construction

Materials intended for contact with food must be corrosion resistant, nontoxic, mechanically stable, and have a surface finish that is not adversely affected under conditions of use.[17]

Toxicity. No toxic construction materials should be used and the relevant legislation must be respected. The traditional stainless steel materials, such as types AISI-304, AISI-316, and AISI-316L, are fully acceptable for most applications (ie, under the conditions that these materials are corrosion resistant). Care must be taken when polymer and elastomer materials are used as they may contain leachable toxic components. The same applies to the use of adhesives, lubricants, and signal transfer liquids. Greases and lubrication oils should comply with §178.3570 of the US Food Drugs Cosmetics Law Reports.[26] The supplier must present evidence that the material is safe for use in contact with food.

Surface Roughness. Product contact surfaces should be smooth enough to be easily cleanable. The roughness (or smoothness) of a surface usually is expressed in μm, as R_a- value.[33] A surface finish of R_a = 0.8 μm is recommended.[1,17] To achieve this quality of surface, polishing or other surface treatment may be required. Cold rolled stainless steel sheet material, used for vessels and for piping, usually has an R_a-value between 0.2 and 0.5 μm and treatment thus is not needed. The surfaces should also be free from imperfections such as pits, folds, and crevices.[17]

Corrosion. To retain the desired smoothness of the surface, the equipment must be resistant to the product under the process conditions and withstand the cleaning procedure (concentration of chemicals at temperature of use for the times needed [eg,. 250 mg/kg sodium hypochlorite at 40° C for 20 minutes]) during the intended lifetime. Corrosion can be minimized by sticking to the concentrations, times, and temperatures specified, and by complete removal of residues (or neutralization if any is left at nonproduct contact surfaces of equipment). Many food products contain chloride and have a pH between 3 and 5, a very corrosive combination. Because in addition contact with product is much longer than contact with cleaning and sanitizing agents, often the rate of corrosion is determined by the product. This should be taken into consideration when selecting materials of construction.

The corrosion resistance of stainless steel is provided for a large part by a thin but effective film of chromium oxide on the surface. If the film is damaged, mechanically or chemically, corrosion of the iron under the film starts. The lifetime of stainless steel can be extended substantially by ensuring that any damage to the chromium oxide film is repaired, which is possible by treatment with oxidizing acids, such as nitric acid. This treatment is called "passivation."[41]

Welds. In principle, for permanent joints welding is the best method. A prerequisite is that welding is done correctly, which requires skilled welders. Not all welding methods can deliver welds of hygienic quality, but typically tungsten-inert-gas welding can. To obtain a good weld, materials must match (in composition *and* in dimensions), and during welding the materials must be fully protected by inert gas and the welding temperature must be correct. Otherwise, welds may seem correct when fresh and polished but will corrode rapidly in use. Bad welds can cause severe problems; therefore, to ensure that welds meet hygienic requirements, it is recommended to follow the European Hygienic Equipment Design Group (EHEDG) guidelines for welding of stainless steel.[22]

Gasket Materials. Traditionally, gaskets are made from rubber and particularly from synthetic rubbers or elastomers. Gaskets used in the food industry differ from those in other industries, in particular in that the gaskets often must be able to withstand a variety of conditions, such as subzero temperatures during processing and above 100° C during sterilization. Moreover, they must withstand a variety of products, such as acid and alkaline solutions as well as oils, at low and high temperatures. Gasket materials may easily impair cleaning and sanitation of equipment. To circumvent these problems, and because of both temperature and corrosion resistance, equipment manufacturers tend to use polytetrafluoroethylene (PTFE) as gasket material in food processing equipment. PTFE, however, lacks resilience. Due to the large difference in thermal expansion coefficient between PTFE and stainless steel, a heat treatment changes the shape of the PTFE gasket and, after cooling down, a crevice occurs (Figure 59–6). For a gasket of 5 mm thickness and a temperature change from 20 to 120° C and back, the crevice may be 36 μm wide (assuming no resilience at all; in practice, the gap will be slightly smaller). It is therefore strongly recommended not to use seals made from nonresilient materials.[39]

In 1996, gaskets and couplings (Figure 59–7) were designed to meet all requirements; they provide a reliable seal without affecting cleanability.[4]

Cleanability

To be cleaned without difficulty, surfaces must be smooth and free from crevices, sharp corners, protrusions, and shadow zones, not only when new, but during the entire functional lifetime.

Influence of Surface Roughness. Although good cleanability is the objective and smoothness is not, for practical reasons usually a maximum roughness is specified for food contact surfaces. Generally, cleaning time required increases with surface roughness.[48] Both the American 3-A organization and the EHEDG specify for food-contact surfaces a maximum roughness of $R_a = 0.8\ \mu m$.[1,17] According to the EHEDG, rougher surfaces can be acceptable if tests have shown that the required cleanability is achieved.[17] Porous surfaces usually are unacceptable.

Crevices. Crevices cannot be cleaned and will therefore retain product residues, which may effectively protect microorganisms against inactivation. In some cases, crevices are unavoidable. This may be the case if slide bearings are needed in contact with product (eg, as bottom bearings of top driven stirrers and as bearings in scraped surface heat exchangers). Their presence should be taken into account when writing procedures for cleaning and disinfection. These procedures may need instructions for partly or total dismantling of equipment or increased cleaning times. In most cases, crevices are the result of incorrect choices when designing (or choosing) equipment. When parts of equipment must be mounted together, metal-to-metal contacts (other than welds) must be avoided as they leave very narrow and deep crevices. Elastomers should be used between metal components but not in the form of O-rings in standard O-ring grooves, as this too will create crevices. The elastomeric material must be mounted in such a way that the seal is at the product side and that, to prevent destruction of the elastomer, excessive compression is prevented. This can be achieved by including design features that align the surfaces of the various parts and provide a metal stop. Figures 59–8 and 59–9 show examples of correct constructions.

Shadow Zones. There is much less transfer of energy to the food residues (soil) in zones in process equipment that are outside of the main flow of cleaning liquids than to the soil in the main flow. Such areas are difficult to clean and should be avoided. If unavoidable, their presence should be taken into account when devising the cleaning procedures. Typical shadow zones are the legs of T-pieces in pipelines used to mount sensors such as pressure gauges and products dividers/directors on conveyor belts.

Cleanability Testing. In case of doubt, the cleanability of equipment may be tested. Currently in Europe there are about 10 independent laboratories[10] that can test the cleanability of relatively small size equipment for closed processing (such as pumps, valves, and in-line sensors), using the EHEDG comparative cleanability test.[31] In this method, all product contact surfaces of the equipment to be tested and of a reference pipe are soiled with buttermilk mixed with spores of a *Bacillus stearothermophilus* strain as an indicator of removal

Grell, et al, Hygienic Pipe Couplings, *EHEDG Document 16*, as summarized in *Trends in Food Science Technology*, Vol. 8, pp. 88–92, Courtesy of European Hygienic Equipment Design Group (EHEDG), Brussels.

of the soil. Then equipment and pipe are subjected to a very mild cleaning procedure so that some soil is left behind in the reference pipe. The number of spores still present after cleaning is a measure of the amount of soil left. The amounts left in the equipment tested and the reference pipe are compared. The method tells the equipment manufacturer whether the equipment tested can be cleaned more easily, more difficultly, or approximately as easily as a straight pipe.

A new method has become available, which is easier to apply, gives results faster, but is less sensitive than the above method. The method also is cheap and may be appropriate in many instances and certainly suitable as a means of preselection, reducing the number of the more expensive microbiological tests required during the development of new food processing equipment. The difference with the microbiological method is that instead of a bacterial spore, a colorant (β-carotene) is used as soil residue indicator.[52]

A consortium of laboratories and industries is developing methods to test the cleanability of larger pieces of equipment, such as homogenizers and scraped surface heat exchangers and very large pieces of equipment, for both closed- and open-process equipment.[32]

Decontamination of Equipment

Protection of Microorganisms by Soil Residues. Microorganisms can be very well protected by soil residues from destruction by heat. Sterilization with steam is dramatically impaired by the presence of soiled crevices.[40] For instance, treatment with saturated steam at a temperature of 120° C for 30 minutes will inactivate all viable *Bacillus subtilis* B1–12 spores on the surface of clean equipment, the D_{120}-value of these spores being approximately 14 s.[45] In soils consisting of normal food constituents, such as protein, sugar, fat, or a mixture of fat and protein, the D_{120} values found were 13 to 28

minutes, at water activities of 0.5 to 0.6. Further, the reduction in number of viable spores in the protein/fat mixture dropped to a factor of 1,000 in a crevice at a distance of 15 mm from the surface. The decrease in degree of inactivation cannot be attributed solely to the slightly lower temperature in the crevice (approximately 117° C, for more than 10 minutes). More important seems to be that the water activity in the soil remains low despite the saturated steam passing the entrance of the crevice. D-values increase dramatically with decrease in water activity.[14] This applies to all types of microorganisms, including aerobic and anaerobic bacterial spores,[14] vegetative bacteria such as staphylococci,[54] and molds such as *Aspergillus* species.[20] Thus crevices may have a very dramatic effect on the sterilization of food processing equipment and hence on product safety. Clearly, it is essential that equipment is clean before decontamination.

Chemical Decontamination of Equipment. Open-plant equipment usually is decontaminated using microbicidal chemicals such as sodium hypochlorite, typically in a concentration of 50–200 mg kg^{-1} (total elemental Cl) at near ambient temperatures for 1 to 10 minutes, and quaternary ammonium compounds at 100 to 200 mg kg^{-1}. To save energy, often closed plants too are disinfected chemically.

Most disinfectants react with soil and become ineffective. It has been observed that chemicals hardly penetrate into crevices of the dimensions discussed above within the time usually allowed for the disinfection of equipment. The addition of surface active compounds does not improve the penetration. Apparently, diffusion is the only mechanism of transport of the disinfectant and this takes too much time. Chemical inactivation of microorganisms in soil present in crevices is simply not possible therefore. This has been confirmed experimentally.[6] This again demonstrates that food contact equipment must be free from crevices. Where crevices cannot be avoided, dismantling to remove soil prior to chemical decontamination is essential.

If closed equipment has to be suitable for decontamination with microbicidal solutions, there should be no air traps (dead areas), such as upwardly pointing legs, which would hamper the solutions to reach all surfaces. Air traps are often found near valves, temperature probes, and pressure gauges. Figure 59–10 shows such an air (and product) trap formed by the incorrect positioning of a pressure gauge on a T-piece. Figure 59–11 shows two layouts of valves and associated pipework for the transfer of product under sterile conditions to an aseptic tank and to protect the product in the tank from contamination while a product line is unsterile. Figure 59–11A shows a common layout of a valve arrangement with large traps, which may be a source of sterility problems; for details see "Sterility Barriers."

To ensure contact of chemical solutions with the inside surfaces of hinges, slide bearings, and dynamic seals (of any type), movable components should be actuated: conveyor chains should run, valves should be opened and closed, and pumps and stirrers should be switched on. For how many times and how long may have to be determined experimentally. The necessary actions must be included in the cleaning and disinfection procedures.

Thermal Decontamination of Equipment. Closed process lines are usually decontaminated by

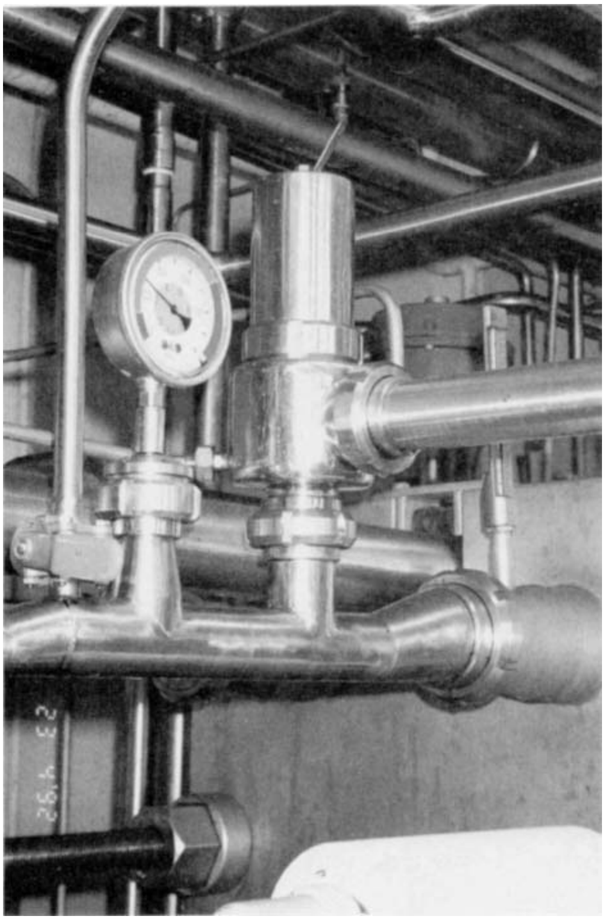

Figure 59–10 Traditional Way of Mounting Pressure Gauges and Safety Valves. Courtesy of Unilever Research Vlaardingen.

thermal methods. If bacterial spores are not relevant (eg, the line is used for pasteurized products), hot water is used. If bacterial spores are relevant, decontamination is done by either steam or hot water (under pressure).

Protection of Microorganisms against Thermal Inactivation by O-rings. Elastomers expand more than 10 times as much as stainless steel. The result is that heating causes an O-ring in an O-ring groove to expand more than the stainless steel by which it is enclosed. The contact surface between the O-ring and the steel increases with the rise in temperature and gradually more microorganisms are trapped between the rubber and the steel.[40] The O-rings thus protect microorganisms in a very similar way to soil residues; the water activity will be lower than intended, resulting in survival.[44] Obviously, the use of O-rings in food processing equipment increases product safety risks and therefore should, in principle, be avoided, unless special precautions are taken. For instance, O-rings of accurate dimensions may be used in equally accurate grooves so that entrapment of microorganisms is prevented and the ring is protected against excessive compression.[4] In many cases, the use of flat gaskets is easier.

Testing Whether Equipment Is Suitable for Thermal Decontamination. The EHEDG has defined standard methods to test the pasteurizability[51] and sterilizability[49] of equipment. These methods should be used if there is doubt whether a piece of equipment that must be free from (relevant) microorganisms before use can be pasteurized or sterilized. In these methods, the equipment to be tested is contaminated with a test organism (ascospores of *Neosartoria fischeri* for pasteurization and *Bacillus subtilis* spores for sterilization). Then the equipment is pasteurized (with water of 90° C for 30 minutes) or sterilized (with saturated steam of 120° C for 30 minutes). Subsequently the equipment is filled, aseptically, with nutrient medium to check for growth of the test organisms.

Preventing Contamination of Product with Liquids Used for Cleaning and Sanitation

Usually it is unavoidable to use chemicals for cleaning and disinfection of food processing equipment. Further, chemicals may be used to destroy unwanted microorganisms. Chemicals used may pose a danger to the safety and quality of the product to be made, however. It is therefore essential that all chemicals used are removed from the equipment before the production is started unless chemicals (such as peracetic acid) leave nontoxic residues.

Drainability of Equipment and Process Lines

To make it possible to remove all chemicals from process equipment, the equipment must be designed to be self-drainable[15]; thus, surfaces and pipes should not be completely horizontal but slope toward drain points and there should be no ridges that may hamper draining. Where it is not possible to build equipment so that proper draining is possible, procedures must be designed to ensure that residues of cleaning and disinfection liquids can be removed in another way. The method used should be well documented and there must be clear instructions. Draining is also important if no chemicals are used because many microorganisms can easily grow in residual water, needing only very minute amounts of nutrients.

Microbial Growth and Process Equipment

If the product is suitable for the multiplication of microorganisms and if microorganisms are present, multiplication will almost always take place, often even if seemingly all possible measures have been taken to prevent multiplication.

Residence Time Distribution. The geometry of equipment influences residence time distribution and there usually are places in process lines, even if correctly designed, where some product is residing longer than desirable. Even if dead areas have been designed out, there is always an amount of product attached to equipment surfaces, even at high liquid velocities. Microorganisms trapped may reside on such surfaces long enough to multiply. With an increase in the number of microorganisms, the numbers washed away with the product passing increase as well.

Biofilms. Depending on the properties of the surface and the types of microorganisms present, with time biofilms may develop that are very hard to remove. Biofilm development may take place on any type of surface and is difficult to prevent if the conditions sustain the multiplication of microorganisms. Many microorganisms, including many pathogens (*Listeria monocytogenes*, *Salmonella typhimurium*, *Yersinia enterocolitica*, *Klebsiella pneumoniae*, and *Legionella pneumophia*) form biofilms, even under hostile conditions such as the presence of disinfectants. Actually, adverse conditions seem to stimulate microorganisms to grow in biofilms.[56,57] Thermophilic bacteria (such as *Streptococcus thermophilus*) can form biofilms in the cooling section of milk pasteurizers, sometimes within 5 hours, resulting in massive infection (up to 10^6 cells ml^{-1}) of the pasteurized product.[21,36] Biofilms shed microorganisms into the passing product. On metal (including stainless steel) surfaces, biofilms may also enhance corrosion, which may result in microscopic holes. Such pinholes are known to allow the passage of microorganisms present in the cooling medium and thus may cause infection of the product. Like other causes of fouling, biofilms will affect heat transfer in heat exchangers. On temperature probes, biofilms may seriously affect the heat transfer and thereby the accuracy of the measurement. On conveyer belts and on the surfaces of blanching equipment, biofilms may infect cooked or washed products, which are assumed to have been made pathogen-free by the temperature treatment received. Biofilms may be much harder to remove than ordinary soil. If the cleaning procedure is not capable of completely removing biofilms that may have developed, decontamination of the surface by either heat or chemicals may fail as biofilms dramatically increase the resistance of the embedded microorganisms. It thus is imperative that product contact surfaces are well cleaned before disinfection. Wirtanen[58] gives an excellent overview of fouling in relation to equipment for the processing of food.

Temperature Gradients. In attempting to prevent the growth of microorganisms in process lines by cooling, one should be aware that at all places where there is activity, energy is converted into heat, causing rises in temperature. The consequence is, that in chilled rooms (of any size) and in pipelines with cooled products, there are spots of higher temperature, where microorganisms multiply and subsequently infect passing product. Typical examples are mechanical seals, where the friction between the static and the rotating part dissipates a considerable amount of energy, and shafts of electromotors, which conduct the heat of the electric drive to the device in contact with the product. The device can be a fan, agitator, drive shaft of a conveyor chain, or rotor of a centrifugal or lobe pump. These effects can be reduced significantly by using barriers made from materials with a low thermal conductivity (eg, polymers or elastomer flanges between the motor and the driven piece of equipment). Cooling may also be applied (eg, in mechanical seals).

Other sources of heat are lights in freezer tunnels and cooling cabinets or any other electric instrument. Usually, it is possible to mount the heat generating part of the light armature outside the cold area, where adequate cooling can also be applied.

Quantification. The subject of growth of microorganisms in process lines has been given considerable attention as it may cause problems of which the origin often is not recognized. The potential importance can be illustrated by calculating the infection of a product as a result of the presence of stagnating product.

If a cell of *Escherichia coli* is trapped in a dead space filled with 5 ml of a slightly viscous low-acid food product at a temperature of approximately 25° C, it may take less than 24 hours for the number of *E. coli* cells to increase to a concentration of 0.2×10^9 ml^{-1}, assuming a doubling time of 40 minutes. If every hour just 1 ml is washed out from the dead space by the passing product, by the end of the first day of production, every hour the product is infected with 200 million *E. coli* cells. If the production capacity of the line is 5 million ml h^{-1}, the average *E. coli* contamination will be 200/5 = 40 ml^{-1}. Many traditional process lines have much larger (often very contaminated) dead spaces, and temperatures as well as growth rates can be higher.

59.3.2 Specific Requirements for Closed Plants

Equipment for Aseptic Processing

Bacteria Tightness. Equipment for aseptic processing must be cleanable, pasteurizable, or sterilizable (depending on product characteristics and whether or not heat-resistant spore-forming bacteria are able to grow in the product) and, in addition, downstream from the heating section of the pasteurization or sterilization plant, prevent the ingress of microorganisms (ie, be bacteria-tight).

Migration of Microorganisms through Microscopic Leaks. Microorganisms may penetrate through very small leaks. There is considerable evidence that microorganisms may pass microscopic openings very rapidly and that pressure differences may retard but not prevent passage, even if the pressure difference is as high as 0.5 bar. *Serratia marcescens* may move at a speed of 160 mm h^{-1}.[47] Motile bacteria may therefore propel themselves against the flow of liquid through a leak. This is particularly so as a layer of several micrometers of liquid along a wall is unlikely to move at all. Microorganisms, motile or not, may also grow through a passage by forming a biofilm on the surface (Figure 59–12). Data on the migration of microorganisms through microscopic passages indicate that the passage of microorganisms through holes of a few micrometers in diameter in a plate of 0.1 mm thickness:[5]

- may be virtually instantaneous if there is no pressure difference
- is hardly affected by a pressure difference of 0.05 bar
- is retarded by a pressure difference of 0.5 bar; *Serratia marcescens* may need approximately 40 hours under such conditions
- *Klebsiella terrigena* (used as nonmotile test organism) may cross within less than 20 hours, with or without pressure difference (of up to 0.5 bar).

In plate heat-exchangers, the high velocity of product between the plates may assist migration of microorganisms through leaks ("vacuum" pump effect).

The above data should be considered when deciding on safe run times, in particular if attempting to increase run times beyond those with which there is long experience. Depending on the type of hazard and the risk, it may be necessary to install a separation loop containing a microbicidal solution between the pasteurized (or sterilized) product and the cooling medium (incoming raw product or cooling water).[38]

Leaks Resulting from Corrosion. Corrosion not only affects the surface roughness of stainless steel, but may also result in leaks. This is the case when the chemically very resistant chromium dioxide sur-

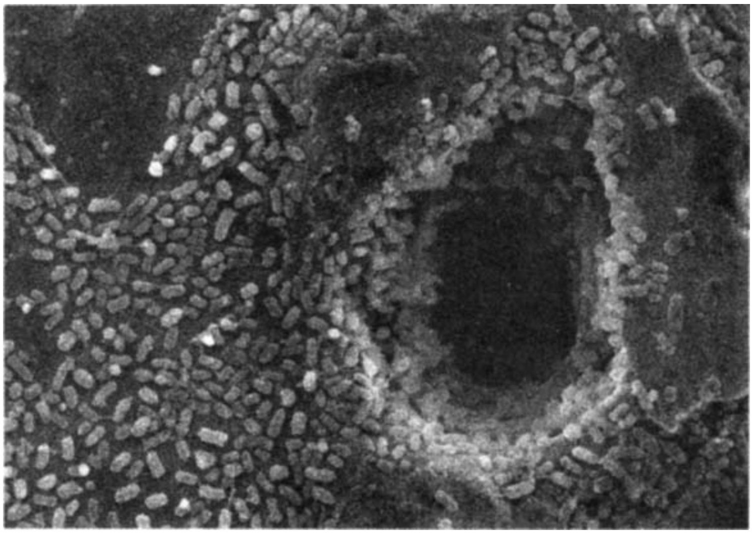

Figure 59–12 Scanning Electron Micrograph showing *Klebsiella terrigena* Growing on the Surface of a 6-µm Hole in a 0.1 mm thick Steel Disk. Courtesy of Unilever Research Vlaardingen.

face layer of stainless steel is damaged, giving chloride (and other) ions access to the iron atoms underneath. This usually results in pitting and development of leaks. Depending on the ionic composition of the product and on the chemicals used for cleaning and sanitation, it may be recommendable to choose other types of metal, such as duplex steels, titanium, or Incoloy.[17] When standing idle, such as on weekends, there should be no chloride-containing liquids left behind in equipment. Such residues are likely to dry out, gradually increasing the chloride concentration and thereby the corrosivity of the residue.

Heat-Exchanger Plates. The thinner the plates, the better the heat transfer and the more efficient the heat-exchanger. Over the past 10 years or so, to save stainless steel (and reduce the weight of the equipment), the thickness of heat-exchanger plates has been gradually decreased. Newly built units usually now have plates of 0.5 mm or even less. During pressing of the plates into the desired shape, locally the plates may be even thinner. This increases the risk of pinholes being present even in new plates. It may be important therefore, depending on the application and the position in the process line, to request that the plates supplied have been tested for the absence of pinholes.

If piston pumps are used to pass the liquid to be sterilized through a plate heat-exchanger, the pulsations generated may cause the plates to bounce with considerable force. The result is cracking of the chromium oxide surface layer. It may be necessary therefore to install pulsation dampeners (of a type that does not create a dead leg). The plates in the regeneration section of a heat-exchanger must be replaced before microscopic holes develop.

Other Heat-Exchangers. Shell and tube heat-exchangers may have the shell welded to the product pipes, in which case corrosion may result from improper welding. Cooling medium may enter the product unnoticed. In other designs, the seal between product pipes and shell is by means of O-rings. Apart from the cleaning and decontamination problems in such cases, the (many) O-rings are difficult to reach for inspection and replacement. Due to aging, but also due to movement of the O-rings in their grooves as a result of thermal expansion and pressure fluctuations, the rate of wear may be considerable and leaks may develop unnoticed.

The problems of poor welding practice apply equally to scraped/swept surface heat-exchangers (SSHE). Additionally, SSHE have shaft seals, which may be of nonhygienic design.

Leaks across Static Seals Caused by Pressure Fluctuations. If elastomer O-rings are used in the usual standard O-ring grooves, pressure differences will cause movement of the rings in their grooves. Thereby the surfaces of the rings alternatingly contact the nonproduct side and the product side of the grooves, transporting microorganisms from the outside to the inside of the equipment (Figure 59–13). Thus such constructions should not be used. Seals should be made as discussed above.

Leaks due to Differences in Thermal Expansion. As can be concluded from the paragraph on nonresilient gasket materials in the section on "Cleanability" above, sterilization of equipment with seals made from nonresilient materials, such as PTFE, is likely to cause gaps of many micrometers wide, enough for microorganisms to pass. Such materials therefore must not be used in equipment to be used for aseptic process lines. If they cannot be avoided because of the resistance to corrosion needed in a certain process step, they must be supported by a sufficiently resilient elastomer (Figure 59–14).

Migration through Dynamic Seals. Axial movement of shafts self-evidently will assist the transport of microorganisms (in a similar way as the O-rings do in case of pressure fluctuations). Not only reciprocating shafts of, for example, piston pumps and lip-seal valves, but also rotary shafts show at least some axial movement. Therefore, if the ingress of microorganisms must be prevented, reciprocating shaft seals should not be in contact with the product side. This can be achieved by separating the shaft seal from the product by means of flexible diaphragms of bellows. Also, equipment without a dynamic seal may be chosen, such as peristaltic pumps, diaphragm (membrane) pumps, and diaphragm valves. Rotary seals might be avoided by using magnetic drives. Although this may be feasible, costs and maximum available torque may be limiting.

Antimicrobial Barrier Systems. Where for whatever reason, dynamic seals cannot be avoided, such as in centrifugal pumps, stirrer assemblies, SSHE, and high-pressure pumps and homogenizers, a double-seal system should be used. The space between the seals is to be flushed with a microbicidal fluid, which may be steam, hot water, or a chemical solution. The seal at the product side should be of

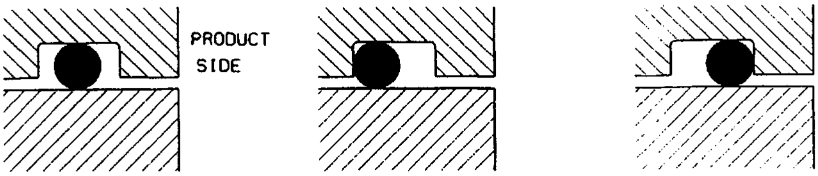

Figure 59–13 Movement of an O-ring in its Groove as a Result of Variations in Pressure. Courtesy of Unilever Research Vlaardingen.

hygienic design and therefore be a well-designed mechanical seal. Some mechanical seal manufacturers can deliver seals in which the complex, difficult-to-clean components are completely enclosed by an easily cleanable diaphragm. The seal at the nonproduct side need not be hygienic and can be of a simpler, cheap (but nevertheless reliable) design. The distance between the two seals must be larger than the axial movement of the shaft, as otherwise microorganisms may be conveyed from the outside to the product side in too short a time for inactivation. Figure 59–15 shows the principle of such an antimicrobial barrier system.

To prevent too fast fouling, a chemical solution is often preferred to steam or hot water. Care should be taken that the chemical chosen is effective and remains effective for the duration of the process run or runs intended. Many antimicrobial chemicals lose their activity in the presence of (too much) organic material, in particular, proteins. Suitable solutions include diluted hydrogen peroxide (>3%), sorbic acid (0.2-0.5%; pH <5.2), and glutaraldehyde (2%; pH8). Leakage of product may cause a change in pH of the solution and the pH often is important for the effect. If too much product has passed the seal closest to the product side, the solution meant to kill microorganisms may actually become a microbial growth medium. Therefore, frequent checking and timely replacement of any antimicrobial barrier liquid are important and should be part of the operating instructions. If a chemical solution is used to prevent contamination of the product processed, the space between the seals must be at atmospheric pressure, which can be achieved easily by ensuring that the return line of the circuit ends in the storage vessel without obstacles. As the product may also be at atmospheric pressure, there is still a risk, although small, of leakage of antimicrobial liquid to the product; therefore, only chemicals that cannot make the product toxic must be used. To be able to detect a leak, the level of the liquid in the storage vessel should be monitored. If leakage occurs, the result will be a very diluted concentration in the product. Assuming a product flow of 1000 kg h^{-1} of product (which is low), passing a seal, which leaks 10 g h^{-1} (which is high), and if the concentration of antimicrobial chemical is 3% (w/w), the concentration in the final product will be 0.3 mg kg^{-1}, which is far below the acceptable concentration of the chemicals discussed.

Mixproof Valves. Normal mixproof valves have two seats, while the space between the seals is open to the environment (Figure 59–16). They have been

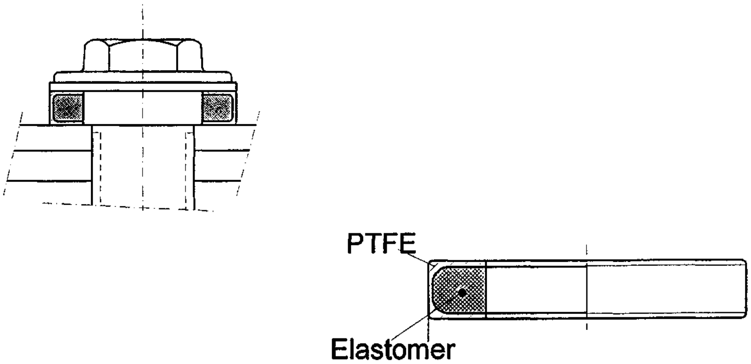

Figure 59–14 Chemically Resistant Gasket with Elastomeric Inlay To Provide Resilience (PTFE = polytetrafluoroethylene). Courtesy of Unilever Research Vlaardingen.

Hauser, R. Mitchell, and K. Sommer.

designed to drain any leakage from the seats. That way such leakages cannot build up pressure so that chemicals used for cleaning do not pass the seat at the product side of the valve. The construction of such valves is rather complex, and many types cannot be drained completely. Water, or worse, product residues, may be sitting on the product side seal for a long time and allow the multiplication of microorganisms. Any microscopic leak of that seal may therefore result in microbial contamination of the product. In aseptic process lines, mixproof valves should be used only if the space between the two seats can be flushed continually with a suitable microbicidal fluid. To avoid the risk of contamination with microorganisms, mixproof valves should not be used to separate raw and decontaminated product unless the antimicrobial fluid between the seats is controlled and monitored continually, to give an alarm in case of failure. A detailed discussion of various types of mixproof valves occurs in the literature.[29]

Sterility Barriers. Figure 59–11 shows two layouts of valves and associated pipework for the transfer of product under sterile conditions to an aseptic tank and to protect the product in the tank from contamination while a product line is unsterile. Figure 59–11A shows a typical sterile barrier. When the plant and tank are sterile and product is to be transferred to the tank, valves 3 and 4 are closed and 1 and 2 opened. If the process plant becomes unsterile and hence it is necessary to protect the product in the tank, valves 1 and 2 are closed and steam purges the short section of pipe between them. A bypass valve also must be fitted such that the back of valve 4 can be steamed to prevent any potential contamination via valve 4. This also prevents condensate accumulating in the steam supply line. A temperature sensor in the outlet line, between valve 4 and the orifice/steam trap, enables the status of the barrier to be monitored and ensures that the barrier temperature is always sufficient. In some cases, an antimicrobial fluid may be used in place of steam within the barrier. Note the potential dead areas. Figure 59–11B shows a similar sterile barrier, but one that is free from dead legs, using an aseptic double seat valve. The design of the valve must be such that the distance between the seals is longer than the stroke of the shaft.[30]

Testing Bacteria-Tightness of Process Equipment. The bacteria-tightness of equipment can be tested by a standardized method,[50] which often is performed in conjunction with the sterilization test described earlier. In this test, equipment is sterilized and filled with a sterile liquid culture medium. The outside of all suspected areas of the equipment to be tested are wetted with a culture of *Serratia marcescens*, a very motile bacterium. This is repeated several times, while any movable component is actuated. If the medium in the equipment remains sterile, it is apparently bacteria-tight.

59.3.3 Decontamination of Air

Airborne Microorganisms

In most environments the concentration of microorganisms in the air ranges between 100 and 1000 m^{-3}; in agricultural areas, the concentration may be much higher. In coastal areas, the concentration often is low. Airborne microorganisms may be single spores, such as conidiospores of molds like *Penicillium* and *Aspergillus*. Bacterial spores, however, often occur as clusters, surrounded by a mixture of inorganic and organic material, remnants of the substrate in which they have developed. High concentrations of vegetative bacteria usually are found close to their origin only, such as near wastewater treatment plants, although some vegetative bacteria, such as some micrococci, are tough enough to survive in air for a long time. Their origin can also be from humans and from raw materials and products during processing. In many instances, airborne microorganisms are associated with dust particles. A recent study[35] showed the aerodynamic diameter of airborne particles containing microorganisms averaged approximately 9 µm.

Decontamination by Incineration

Air can be sterilized within less than a second by heating to a temperature of 350° C.[23] At such a temperature, organic materials are destroyed together with all known microorganisms. Incinerators, therefore, are probably more reliable than filters, provided that their design guarantees that all air is heated to the required temperature; therefore, an incinerator must be equipped with a reliable temperature control system. Although this method does not require much energy because of the low heat capacity of air, for most applications the method is more expensive than filtration.

Decontamination of Air by Filtration

Filtration is based on various mechanisms of particle retention. Depth filters usually rely on entrapment of particles in a labyrinth of fibers and electrostatic attraction. Membrane filters rely on pore sizes. Membrane filters have a much higher resistance than depth filters and are therefore not normally used in the food industry. Industrial high efficiency particulate air (HEPA) filters are made from corrugated sheets of compact fibrous material that is mounted in cartridges using a glue or resin. The cartridges in turn fit in the filter houses that are mounted in the air ducts (air for clean rooms) or pipelines (process air). As a leak may virtually annihilate the effect of the filter (if 1% of air is passing between housing and cartridge, the reduction in concentration of microorganisms will be less than 100-fold), the installation of the cartridges must be done very carefully, with particular attention to the gaskets used to seal between cartridge and housing. For critical applications it may be advisable to use two filter assemblies in series and/or to have the filter assemblies tested before installation and use.[34] The literature discusses air treatment of clean rooms for food processing, covering such aspects as choice of filters, filtration efficiency, and the testing and maintenance of filters.[3,7,37] Chapter 15 of Wang[55] "Air Filtration, Air-Handling Units and Packaged Units" also provides considerable useful information on filtration in air conditioning and refrigeration installations.

59.3.4 Packaging

If a product has been produced and has been pasteurized or sterilized correctly, it must be ascertained that the next step, packaging, does not adversely affect the condition of that product; therefore, care must be taken that no unacceptable recontamination takes place during the transfer of the product to the packaging equipment and during the packaging operation itself. If the process line and the packing machine are cleaned and decontaminated independently, which usually is the case, the connection between the two must not impair the hygienic condition achieved. In case of aseptic packing, making the connection must also be done in an aseptic way. This requires that the connection made is thoroughly decontaminated before starting the flow of product. Equally, during cleaning and decontamination of the packing machine the process line or aseptic storage tank must be protected against contamination by the cleaning chemicals and *vice versa*.

The Influence of the Environment of the Packing Machine

The risk of contamination of a surface with microorganisms will always be proportional to the concentration of microorganisms in the immediate environment and the time of exposure. Therefore, to reduce the risk of infection during packaging, it may help to reduce the concentration of microorganisms in the environment and to keep the time of exposure to the environment of the product side of the packing material and the product to a minimum. The sedimentation velocity of microorganisms present in the air is in the order of $v_s = 0.003\ m\ s^{-1}$.[35] A simple calculation shows that the infection of a product by microorganisms in the air can indeed be significant: if the concentration in the air is $x_{air} = 1000\ m^{-3}$, the time of exposure is $t = 5$ seconds and the exposed surface area is $A = 0.01\ m^2$ (ie, 100 x 100 mm), the number of microorganisms settling on that surface will be:

$$n = v_s \cdot x_{air} \cdot t \cdot A = 0.15$$

In words, under the conditions assumed in this example 15% of the surfaces exposed will be infected with one microorganism. This may or may not be acceptable in case of hygienic packing; it certainly will be unacceptable for aseptic packaging. The risk of contamination may be reduced by simple measures, such as the installation of a tunnel over the area where the packing material and the products are exposed. If this would not be effective enough, sterile air may be supplied to the tunnel.

The Influence of the Microbiological Quality of the Packing Material

The packing material may contain more microorganisms than desirable. If so, improvement of the quality may be negotiated with the manufacturer. A better quality may be obtained following a number of measures to be taken by the manufacturer, such as a cleaner environment in the factory, more hygienic handling of the material, removal of static electricity, better protection during transport, and avoiding the use of heavily contaminated cartons for packing of the packaging material. It may be more secure to decontaminate the packing material on the packing machine just before filling. This may be done using hydrogen peroxide, heat, UV light, or other treatments, either individually or in combination. If acid products or products with a sufficiently low water activity are packed, the use of moist heat can be attractive as it seems to be effective against vegetative microorganisms without using chemicals.[46]

To prevent contamination of packing material, the following precautions may be needed:[43]

- protecting (by the packing material manufacturer) the packing material
- cleaning of the outer material before opening
- removing dust from the air
- avoidance of manual handling
- keeping the packing material storage area clean and dry
- removing static electric charges.

Hygienic Filling and Packaging

When packing microbially unstable products, which are not to be in-pack sterilized or pasteurized, it is essential that the residence time of the product in the packing machine and the temperatures in the machine are controlled so that microbial growth does not occur. This is particularly important during production stops. If the duration of stops exceeds a certain time, the packing machine may have to be cleaned and decontaminated before restarting. When cleaning filling and packaging equipment used for dry products, wet cleaning should be avoided; dry cleaning methods are discussed in Chapter 58.

Condensate formed during filling of relatively hot products or formed on filling nozzles during filling of products that are at a low temperature relative to the ambient temperature should be prevented from contaminating the product. Where possible, moving parts of fillers should be cleaned outside the production area. The build-up of product around the filling nozzle is impossible to avoid, and is a potential source of contamination of the product flow; such build-up may determine the run time of the filling equipment before cleaning is necessary.

Aseptic filling and packaging requires the maintenance of commercial sterility of the product during filling and packaging. The design and operation of aseptic packer is considered in Cerf and Brissenden[9] and the control of sealing of packs in Mostert et al.[42]

59.3.5 Examples of Equipment of Wrong and Correct Design

General

Typical examples of designs that may easily result in microbiological problems are given in Figures 59–17 through 59–21. The use of bolts should be avoided, but where unavoidable, at least the crevices they create should be sealed (Figure 59–17). Sharp corners should be avoided (Figure 59–18); exceptions are constructions where the sharp corner is continually swept such as in lobe pumps. Welds must be smooth when made and remain smooth in use. This requires skilled welders doing a good job. Figure 59–19 presents schematically welds easily causing hygiene risks as well as correct welds for the same purpose. Figure 59–20 shows the results of improper welding, such as misalignment, lack of penetration, and lack of gas shielding. Figure 59–21 shows the results of correct welding.

Open Plant

Figure 59–22 shows how drainable equipment should be designed and installed. Figure 59–23

- Diagram D (left) shows a raised and open walkway over equipment and the potential for contamination from personnel using the walkway
- Diagram D (right) shows a better, enclosed design.

Figure 59–24 shows various hygienic and unhygienic designs of conveyor belt. It is very important that conveyor belting does not absorb moisture as this will lead to microbial growth and contamination of product carried on the conveyor. Once microorganisms have colonized the inner fabric of the belt, it is impossible to kill them. Damaged belts must always be replaced and their edges sealed. Even when conveyors are properly designed and maintained, cleaning may still be difficult; thorough

cleaning and inspection of cleanliness after cleaning are essential.

Curiel discusses many details of the hygienic design of open plant.[19]

Closed Plant

Figure 59–25 shows how a lid of a tank, intended to protect the product, may accumulate dirt that will enter the product in the tank when the lid is opened, next to a correct design. Policy should be that tanks are not opened at all during production unless absolutely necessary. Figures 59–26, 59–27, and 59–28 present ways to ensure that closed equipment can be drained.

A common mistake in the construction of bypasses for positive displacement pumps, causing a large dead area filled with product, is shown in Figure 59–29. With almost the same components, dead areas can be avoided completely. Figure 59–30 shows wrong and correct designs of couplings, with attention to (mis)alignment and the correct use of gaskets. Flexible hoses frequently are used to connect mov-

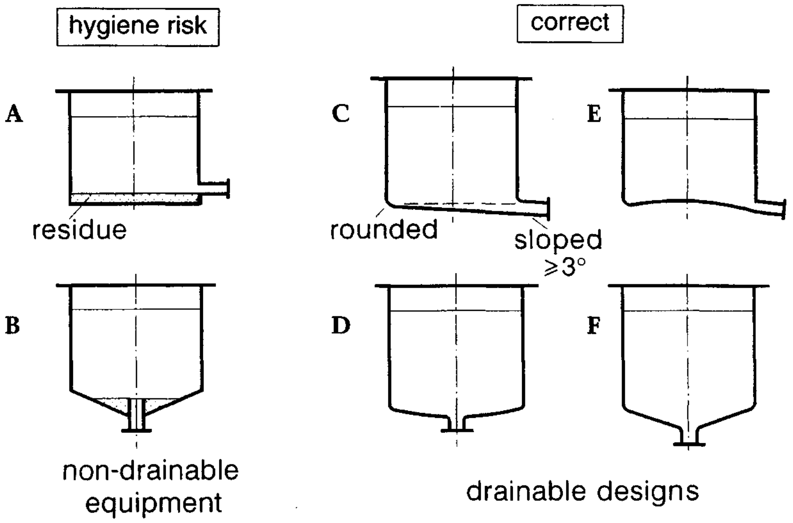

Figure 59–22 Drainability of Equipment. In **A** and **B** discharge outlets above the lowest level of the equipment prevent self-draining. ing and static parts of process lines (eg, movable dosing heads on filling machines). Figure 59–31 shows the noncleanable crevice created by the traditional way of mounting hoses to pipes and how this can be done correctly (ie, without crevices). It is strongly recommended that the EHEDG guidelines on closed plant equipment are followed.[18]

59.4 DESIGN OF PROCESS LINES

59.4.1 General

The choice of equipment used to build a process line should be based on a hazard assessment, which takes into account the microbial susceptibility of the product, the stage in the process and the required cleaning frequency, and the conditions of storage and the shelf life of the product. For handling raw materials, straight from the field, the requirements will be different from those for washed or cooked product. The aim should be that none of the process steps decreases the microbiological quality of the product. This also requires measures to prevent cross contamination (see also Section 59.2.1). Having selected the appropriate pieces of equipment for a process line, it is extremely important to ensure that the design of the whole line allows good cleanability and sanitizability (disinfection, pasteurization, sterilization) and for aseptic processes bacteria-tightness requirements are retained.

Cleaning

It is essential that the cleaning program ensures that all parts of the process line are cleaned, and that all components and all product contact surfaces are also appropriately cleaned. In practice, this may mean that equipment has to be dismantled for access by brushes or water lances. In closed process lines, the cleaning fluids may have to be circulated several times and, during cleaning, movable parts (such as shafts of valves, stirrers, scraped surface heat exchangers, and pumps) need to be actuated a number of times or for a certain period of time. In particular, valves must be open to be able to clean their seats, and stirrer shafts must rotate to have soil removed from within, for example, the bottom slide bearings. These actions will increase the total cleaning time, and it is tempting to reduce the times for the various steps. As soil residues effectively hamper inactivation of microorganisms, doing so may have detrimental consequences.

In the design of a closed cleaning system, variations in dimensions in the pipework must be taken into account. The capacity of the cleaning pump(s) must be chosen to cope with the largest cross section to be cleaned in order that the velocity of the clean-

Temperley, 1995, Hygienic Design of Equipment for Open Processing, *EHEDG Document 13*, as summarized in *Trends in Food Science Technology*, Vol. 13, pp. 305–310, Courtesy of European Hygienic Equipment Design Group (EHEDG), Brussels.

ing fluid is not lower than that intended in any part of the process line. Effective cleaning requires a velocity of cleaning liquid of 1.5 m s^{-1}. Lower velocities may dramatically increase the time required for cleaning.[48]

Gould[28] presents a very useful overview of cleaning and sanitation of both open and closed plants. It is strongly recommended to design a cleaning system in consultation with a specialist cleaning company.

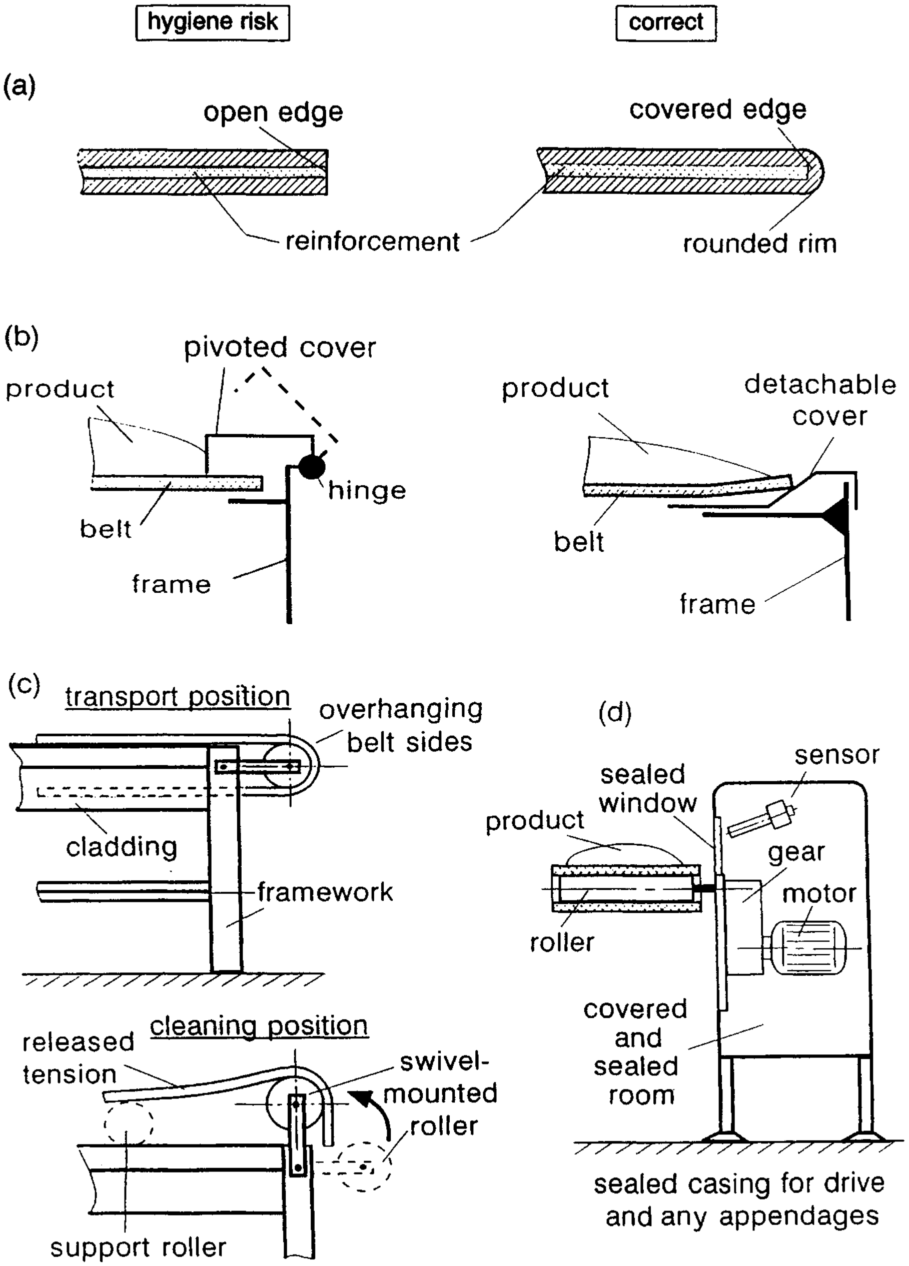

Figure 59–24 Examples of Incorrectly and Correctly Designed Conveyor Belts. *Source:* Reprinted with permission from G.J. Curiel, G. Hauser, D.A. Temperley, 1995, Hygienic Design of Equipment for Open Processing, *EHEDG Document 13*, as summarized in *Trends in Food Science Technology*, Vol. 13, pp. 305–310, Courtesy of European Hygienic Equipment Design Group (EHEDG), Brussels.

Decontamination

A clean process line can be readily decontaminated, provided that all product contact surfaces receive the correct treatment. If heat is used, not only the temperature needs to be taken into account, but also the available water (a_w). Thus if steam is used, it must be assured that the steam is saturated. It must also be known how long it takes for the coldest spot in the process line to reach the required temperature. As discussed under thermal decontamination of process equipment, even if clean, surfaces may remain dry if protected by elastomers; hence the decontamination procedure will be ineffective. This will occur

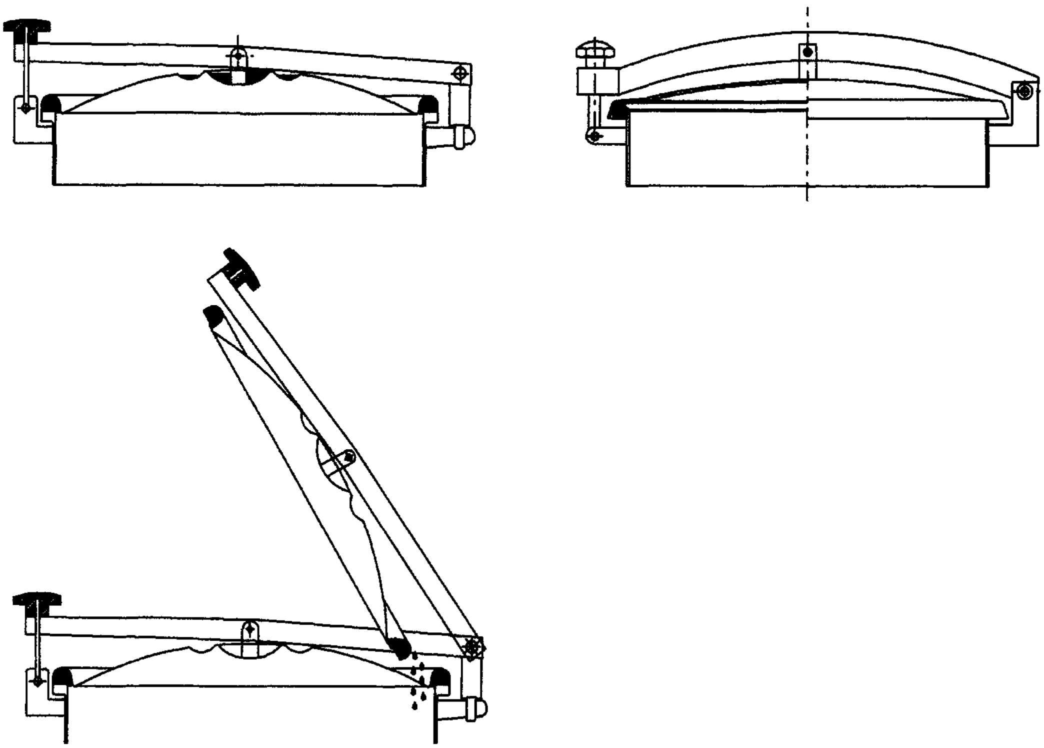

Figure 59–25 Examples of Tank Lids (Manhole Hole Cover). The lid on the left is a poor design and dust, etc., accumulating on the cover will fall into the tank when the cover is lifted. The manhole cover on the right is a better design. Courtesy of Unilever Research Vlaardingen.

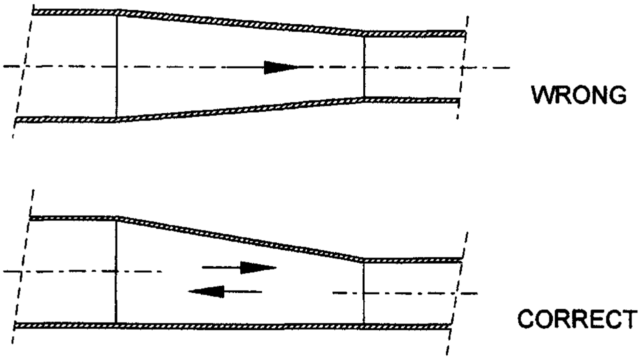

Figure 59–26 Use of Concentric and Eccentric Reducers. Concentric reducers in horizontal pipelines may hamper draining, depending on the direction of the flow. An eccentric reducer, properly installed, will not affect draining, independent on the direction of the flow. *Source:* Reprinted with permission from G.J. Curiel, G. Hauser, P. Peschel, et al., Hygienic Design of Closed Equipment for the Processing of Liquid Food. *EHEDG Document 10*, as summarized in *Trends in Food Science Technology*, Vol. 4, pp. 375–379, Courtesy of European Hygienic Equipment Design Group (EHEDG), Brussels.

if valves are closed. Thus, valves must be opened long enough to ensure that the seat is properly freed from relevant microorganisms; as with cleaning, this may require circulation of the heating medium through the open valve.

Dead ends in pipelines may hamper decontamination by heat or chemicals. If hot water is used to pasteurize a process line, an upward-pointing leg of a T-piece will trap air, thereby reducing the rate of heat transfer and causing the decontamination of the dead leg and what is connected to it to fail. If a process line is sterilized with steam, an upward-pointing dead leg, if clean and not too long, will probably be decontaminated properly, as steam will condense on the surfaces of the leg and fall down to let more steam condense and give off its energy. With steam sterilization, downward-pointing legs give problems. Here condensation will be collected in the leg and hamper heat transfer: the temperature thus will be too low for complete sterilization (unless the presence of the leg has been taken into account in defining sterilization procedures). A properly designed

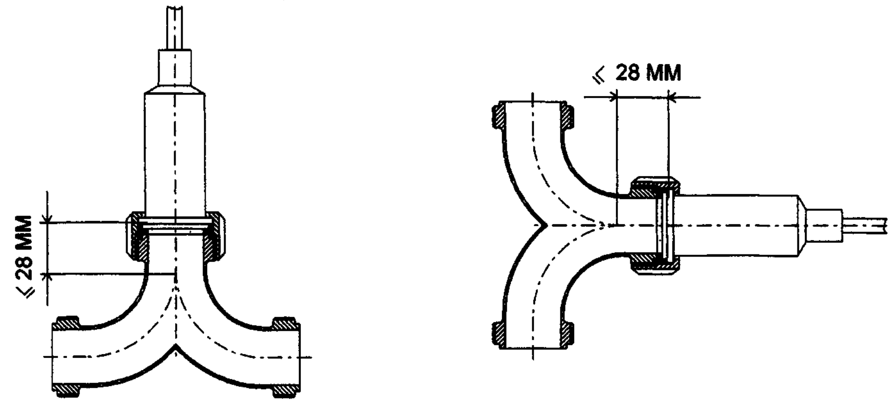

Figure 59–27 Use of Swept Tees. These avoid dead areas and thus facilitate cleaning but if mounted in a horizontal pipeline, they hamper drainage. Swept tees must be used in vertical pipelines only. *Source:* Reprinted with permission from G.J. Curiel, G. Hauser, P. Peschel, et al, Hygienic Design of Closed Equipment for the Processing of Liquid Food. *EHEDG Document 10*, as summarized in *Trends in Food Science Technology*, Vol. 4, pp. 375–379, Courtesy of European Hygienic Equipment Design Group (EHEDG), Brussels.

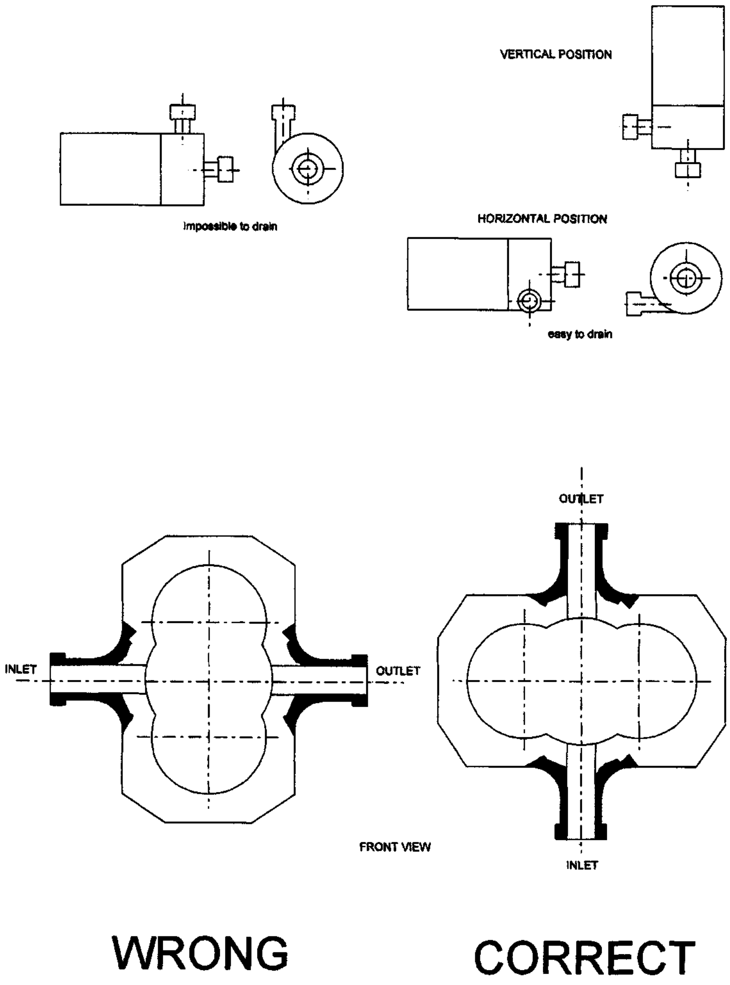

Figure 59–28 Positioning of Centrifugal and Lobe Pumps. It is important to position centrifugal (top) and lobe (bottom) pumps in such a way that they are drainable (right). Courtesy of European Hygienic Equipment Design Group (EHEDG), Brussels.

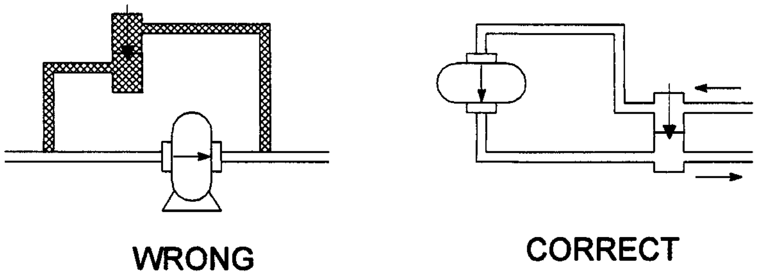

Figure 59–29 Location of Relief/Bypass Valve for a Positive Displacement Pump. The pressure relief/bypass valve for the positive displacement pump shown at left has a dead leg with a large amount of product (shaded area) when the valve is closed, as shown (note also that the pump is not in a position that allows draining). An almost identical valve, mounted as shown in the arrangement shown at right, avoids dead legs in the bypass and allows draining of the pump. *Source:* Reprinted with permission from G.J. Curiel, G. Hauser, P. Peschel, et al, Hygienic Design of Closed Equipment for the Processing of Liquid Food. *EHEDG Document 10,* as summarized in *Trends in Food Science Technology,* Vol. 4, pp. 375–379, Courtesy of European Hygienic Equipment Design Group (EHEDG), Brussels.

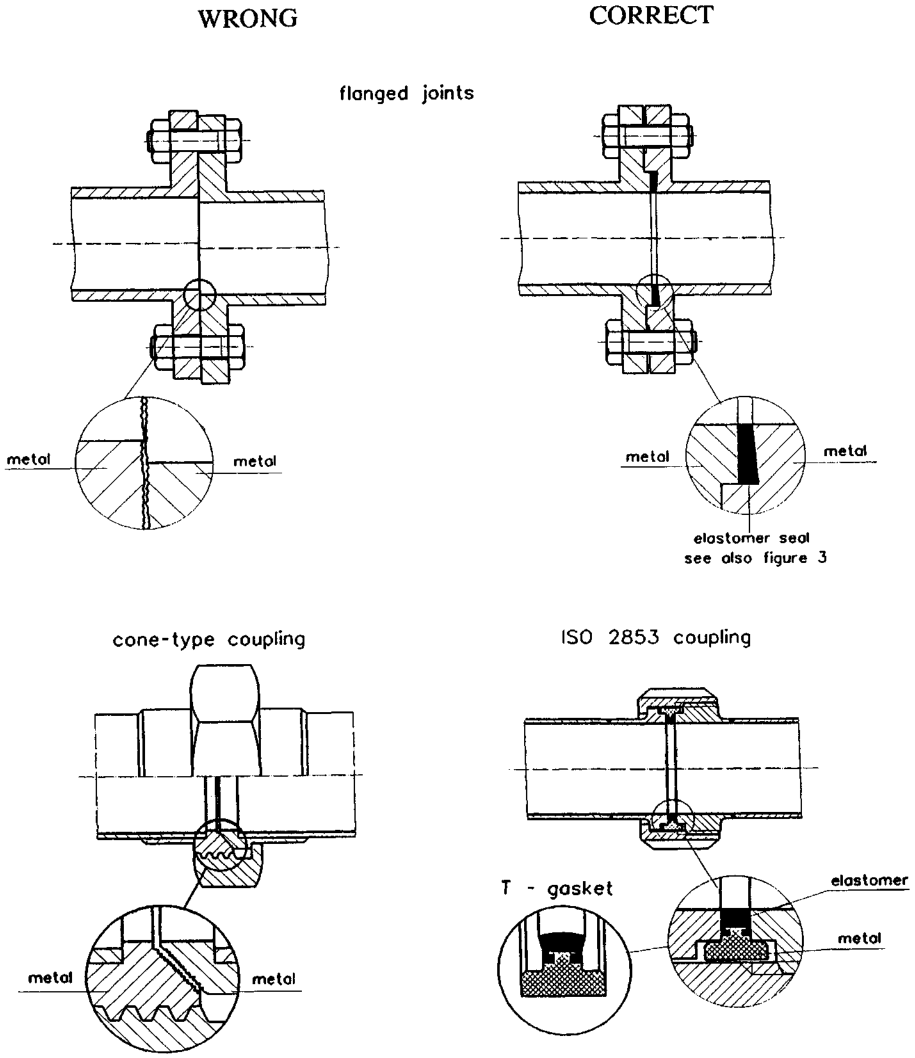

Figure 59–30 Design of Pipe Coupling. The pipe couplings on the left seal between two metal surfaces and therefore have crevices, which cannot be cleaned and are unlikely to remain bacteria tight. The couplings shown on the right provide a permanent seal and are free from crevices. Courtesy of European Hygienic Equipment Design Group (EHEDG), Brussels.

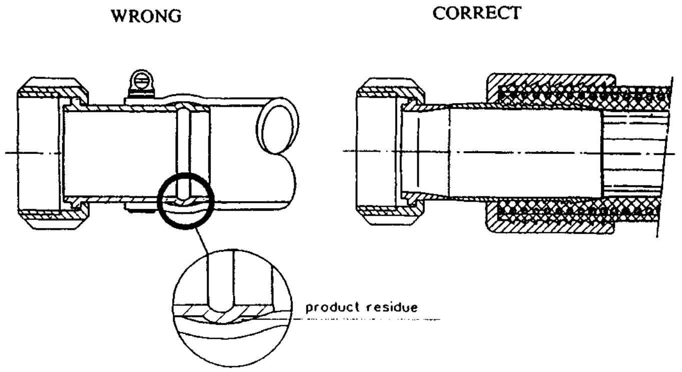

Figure 59–31 Clamping of Flexible Connections. These must be clamped in such a way that no product will be trapped between the hose and liner. Courtesy of European Hygienic Equipment Design Group (EHEDG), Brussels.

food processing line therefore should not have unnecessary dead legs. Those that are unavoidable should be in the correct position for the selected decontamination treatment.

Drainability

It must be ascertained that the self-draining characteristics of the equipment used to build the process line are retained. Often equipment can be drained only in certain positions (Figures 59–26 and 59–27) and this must be taken into account in designing process lines. Also the way the equipment is interconnected must not hamper drainage. The use of isometric three-dimensional drawings can be of great help as they will make it easy to see where draining will be hampered, which often is very difficult to see with two-dimensional drawings.

Tables, conveyor belts, and pipelines must be supported to the extent that pooling of water is prevented. If it is not possible to make a large surface or a long pipeline self-draining, extra drain points must be created. Operators must be instructed on how to use such drain points, particularly if it is necessary to dismantle or loosen components (such as pipe couplings) to allow drainage, requiring tightening or reassembling prior to resuming production.

59.4.2 Specific Requirements for Closed Processes

General

The equipment used in process lines not intended for sterilized products must at least be pasteurizable; chemical disinfection is not usually used for closed plant. Downstream from the heating section of any sterilization plant, hygiene requirements may differ depending on the stability and shelf life of the product. If the sterilized product must have a long shelf life at ambient temperature, all equipment must be sterilizable. However, if the sterilized product is intended for a limited chilled shelf life, it may be sufficient if the equipment is pasteurizable. Long shelf-life products, whether made microbially stable by sterilization (low-acid products of high water activity) or by pasteurization (acid products or products with a sufficiently low water activity), must be protected against recontamination after the heat treatment and thus require equipment that is bacteria-tight. Requirements for the production of pasteurized foods will be found in the literature.[38]

Bacteria-Tightness

Care must be taken that the connection of a dedicated cleaning system to a line intended for aseptic processing does not break the bacteria-tightness of the line. Unless the cleaning system is physically separated from the process line after cleaning, mixproof valves must be used between the cleaning system and the process line (see Section 59.3.2). To prevent the accumulation of dirt and the growth of microorganisms on the nonproduct side of the valve seat closest to the product, the space between the two seats of the valve must be flushed with an antimicrobial fluid. If the product in the process line is not too heat-sensitive, steam or hot water may be used for this purpose. Otherwise, a safe antimicrobial chemical should be used.

59.5 LEGISLATION

The European legislation on food hygiene[15,16] is firm and clear with respect to its objectives; the same applies to legislation in the US.[24–26] Such legislation does not give the details on how to comply but sets down what objectives should be achieved. The initiatives and responsibilities for achieving these standards are left with the manufacturers of food as well as with the suppliers of the machinery used to produce the food. To assist the industry to develop and design hygienic processing lines and equipment, the 3-A organization was founded in the US in 1927. In this organization, equipment manufacturers, food processors, and food inspectors work together to define the requirements for the safe manufacture of food products. Many standards and recommendations have been published. In 1989 the European Commission mandated the European federation of standardization organizations (CEN) in Brussels to produce standards on the hygienic aspects of food processing machinery. Since then, much work has been done by CEN's technical committee 153 and its many working groups and many standards have been prepared. The EHEDG[2] also has published a whole series of publications describing how to comply with hygienic requirements for the safe production of food. In addition, the EHEDG has published "standard" test methods, which can be used to verify whether equipment complies with requirements for hygienic or aseptic operation of food plants; 10 independent institutes in Europe will test equipment according to the EHEDG recommendations.[10] The 3-A and the EHEDG have worked together since 1992, with the objective to harmonize principles and requirements between Europe and North America. The International Dairy Federation also is active in the area of hygienic design of dairy plants.[9]

59.6 CONCLUDING REMARKS

Although in the past 20 years or so much food processing equipment has been designed incorporating sound hygienic design features and many factories have been built with a good understanding of their hygienic design needs, there are still many examples of new designs where there is clearly lack of understanding of the basic principles of hygienic design. To a large extent this is due to lack of awareness. Many individuals with responsibilities for the handling and processing of food have little understanding of basic hygiene measures. This results in many hundreds of thousands of food poisoning incidents per year. This ignorance applies to the entire food chain, from the farmers who grow the food, to the processors and manufacturers who make the food products, to the retailers and caterers who deliver the final product to the consumer and, indeed, includes the consumer, who handles the food in the home. There is a need for those involved in the food chain to receive better education and training in food hygiene and for better cooperation among those involved in the design of new processes and food processing equipment and premises and those that are responsible for managing food operations. The globalization of food supplies, extension of food chains, and the trend toward more convenience, less processing, and fresher tasting products will require the application of even better hygienic designs and practices.

Developments in electronics will result in sensors becoming available that are able to measure minute changes in physical parameters, including temperature, pressure, light, sound, and ultrasound. These developments are expected to play an increasingly important role in the control of food processes. Appropriate research and development will lead to devices that will warn when fouling starts or approaches the acceptable limit, when cleaning of critical surfaces is completed, when filters leak or become too resistant, when deviations from the expected flow and direction of air occur, and when the concentration of particles in the air is increasing. Gradually, such devices will tell the plant operator when to initiate which actions to ensure maximum product safety and quality. Robots will also take over many of the roles of the food operative, being able to operate under a much wider range of inimical conditions than humans.

Appendix 60–A Some terms used in statistical analysis and sampling

60.1 INTRODUCTION

The accuracy and reproducibility of results obtained from any analysis—physical, chemical, or biological—will be dependent on a number of factors associated with the methodology, the equipment, the analyst, and the extent to which the sample analyzed is truly representative of the material under examination. To obtain a reliable estimate of the characteristics of the material under test, it is essential to analyze a number of replicate samples. This is of particular importance when materials of biological origin are analyzed for microorganisms that may not be distributed randomly throughout the product. Hence, the statistics of microbial distribution introduce an overlay onto the already complex statistics of sampling and analysis. The statistical terms used in this chapter are defined in Appendix 60–A.

60.1.1 Microbial Distributions in Foods

A bacterial cell occupies a volume of approximately 1.2 μm^3; hence in a sample of 1cc of a well-mixed liquid, the relative volume occupied by 10^6 bacteria would amount to only approximately 0.0001% of that sample. In such a sample, it would therefore be reasonable to assume that the bacteria would occur randomly; that is to say, that the distribution of bacterial cells would be expected to follow a Poisson distribution. Since bacteria replicate by cell division, it would also be realistic to expect that many cells will occur as small clumps or associations, each of a variable number of cells. Hence a sample of a liquid, such as milk, might contain both randomly distributed individual cells and randomly distributed clumps of variable numbers of cells. Traditional microbiological procedures, such as mixing, homogenizing, serial dilution, and plate counting, may disrupt some of these clumps, while others may remain intact. A standard plate count procedure would therefore generate colonies that grow either from individual cells or from a clump of cells, hence the desirability of reporting such data in terms of colony forming units (cfu) rather than numbers of bacteria.

To obtain a representative sample from a bulk of liquid (eg, a milk churn, a tanker, a silo) would require significant effort to ensure that the liquid was intimately mixed before removal of a sample for analysis. As the volume of bulk liquid increases, the difficulty of ensuring effective mixing becomes ever more difficult. For a dry food material consisting of individual particles (eg, grain, nuts, flour), the difficulty of ensuring a truly representative sample is increased further, and when solid foods are examined (eg, meat, vegetables, compound food products), the impact of microbial distribution is likely to present yet more complexity. In such circumstances, and especially where growth of microorganisms may have occurred on or within the food, the importance of taking sufficiently large samples properly to assess the likely level of microbial contamination and/or the occurrence of specific microbes cannot be overstressed.[28,30] Similar situations pertain to surfaces, both of foods and process plant. Contamination of an unclean surface will result in opportunity for some microorganisms to grow if other environmental conditions are appropriate; at any specific temperature, some organisms may die, some will remain as single cells, while others will form microcolonies (Figure 60–1). If such a surface is subjected to ineffective cleaning and sanitation, some of those organisms will be killed, others will be sublethally damaged, and others (possibly within a micro-colony) may remain viable. Hence, the distribution of the organisms will change from random to a more complex distribution, indicating nonrandomness, such as the negative binomial distribution. Figure 60–2 illustrates the different distribution curves for Poisson,

Figure 60–2 continued (C) Poisson, (D) Negative Binomial

binomial, negative binomial, and "normal" distributions with low mean (average) values.

Why is it important to understand the nature of microbial distributions? First, if analytical data are to be compared, then it is essential that the individual sets of data come from populations having similar distribution characteristics. Second, most statistical tests of difference and significance are based on the concept of the "normal" or Gaussian distribution. Microbial and other data can be "normalized" by transformation such that the transformed data follow a distribution that approximates to "normal." Most colony counts yield data that, after transformation by the use of logarithms, conform approximately to "normal"—hence, the expression "a log normal distribution" (Figure 60–3). However, if a genuine random distribution occurs, the normalization of the data is best done by taking the square root of the original data value (ie, $\sqrt{x}$, where "x" is the value determined).[14]

The principal characteristics of some different statistical distributions are summarized in Table 60–1, and the interrelationship between the different distributions is illustrated schematically in Figure 60–4. The binomial distribution (which is important in defining sampling probabilities, qv) is characterized by having a population distribution variance smaller than the population mean value; by contrast, in the negative binomial distribution the variance is greater than the mean; and in the Poisson or random distribution, the mean and variance are equal. The Poisson distribution is a "limiting" form of the binomial distribution in which the probability (p) of an event occurring is very small (eg, the incidence of bacteria in a defined aliquot of liquid). The binomial and Poisson distributions are discrete or discontinuous distributions, whereas the normal is a continuous distribution. For further information on

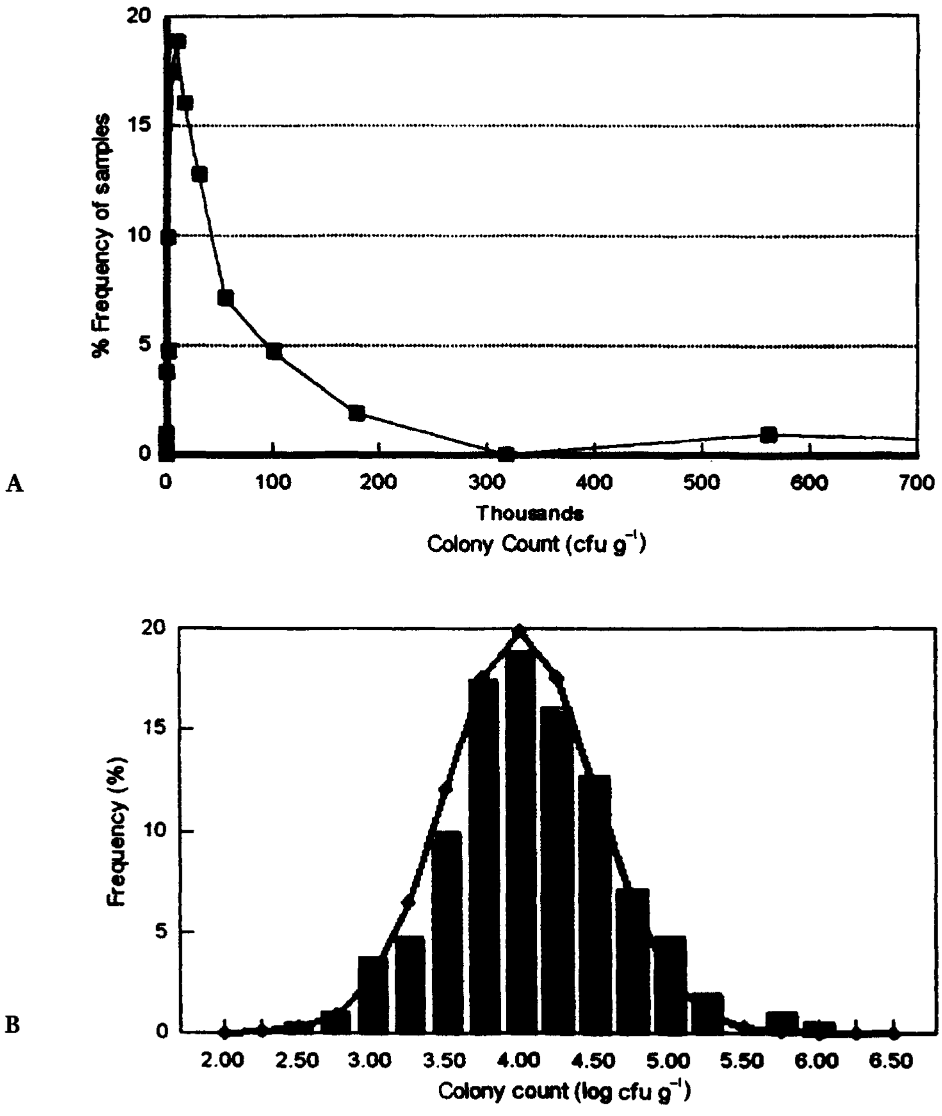

Figure 60–3 Distribution of Colony Counts from a Food Sample (A) before and (B) after logarithmic transformation. A shows the frequency distribution curve from replicate sample units plotted on a linear scale. Note the concentration of data points at the lower end of the ordinate. B shows the same data after logarithmic transformation plotted as a histogram and overlaid with a normal distribution curve.

Table 60–1 Some Characteristics of Continuous and Discrete Distribution Functions

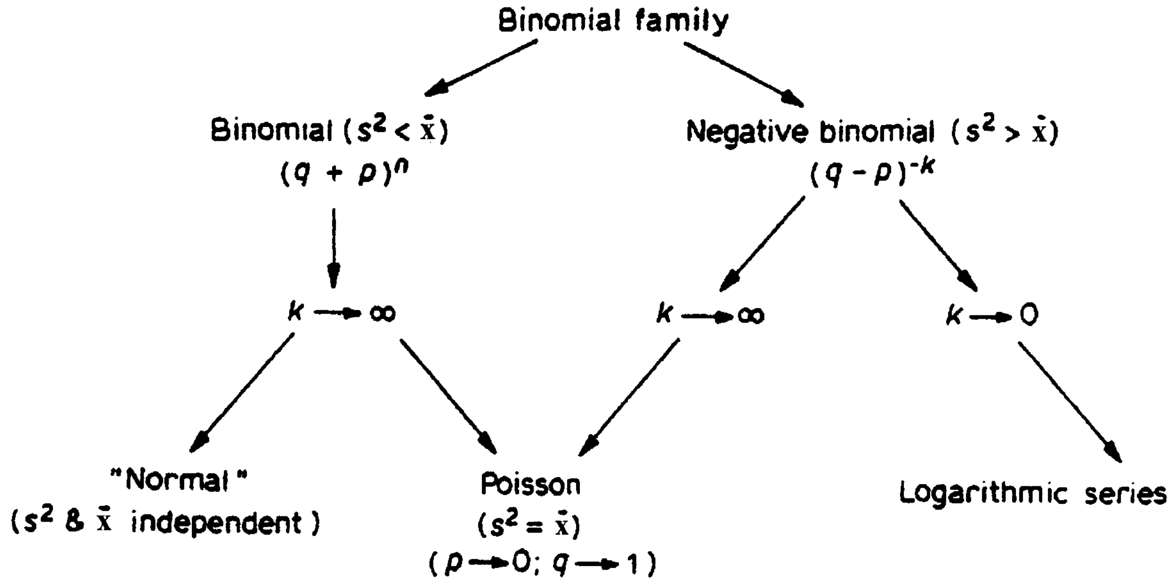
Name	*Domain*	*Probability Density Function f_x*	*Restriction on Parameters*	*Mean*	*Variance*
Normal (Gaussian)	$-\infty < x < \infty$	$(1/\sigma\sqrt{2\pi}) \exp [-\tfrac{1}{2} (x - m)/s^2]$	$-\infty < x < \infty$ $0 < \sigma < \infty$	μ	σ^2
Binomial	for $x = 0, 1, 2, \ldots, n$	$\binom{n}{x} p^x (1 - p)^{n-x}$	$0 < p < 1$ $q = 1 - p$	np	npq
Poisson*	for $x_n = 0, 1, 2, \ldots, \infty$	$e^{-m} . m^x / x!$	$0 < m < \infty$	$\lambda = m$	m
Negative binomial	$x_n = 0, 1, 2, \ldots, \infty$	$\binom{n + x - 1}{x} p^n (1 - p)^x$	$n \geq 0$ and $0 < p < 1$ ($p = 1 / Q$ and $1 - p = P/Q$)	nP	nPQ

*Limiting from a binomial as $p \rightarrow 0$ and $q \rightarrow \infty$

distributions, refer to standard statistical texts (eg, Bowker,[7] Rahman,[38] or Jarvis[28]).

To assess whether a set of microbial counts follows a particular distribution, it is necessary to test the hypothesis that the data conform to, for example, a Poisson distribution, by comparing the distribution frequency of the data with the expected distribution frequency based on the mean value and variance of the experimental data. The "goodness of fit" between the theoretical (expected) and actual data can be tested using a χ^2 test, where:

$$\chi^2 = \Sigma \frac{(O - E)^2}{E}$$



$\bar{x}$ = mean; s^2 = variance; p = probability of success at each trial; q = 1 - p; n = number of trials; k = distribution constant; → means tends to (e.g. p → 0 means as p tends to zero) and ∞ = infinity.

Figure 60–4 Inter-relationships between Frequency Distributions. *Source:* Reprinted with permission from B. Jarvis, Statistical Aspects of the Microbiological Analysis of Food, *Progress in Industrial Microbiology,* Vol. 21, p. 30, © 1989, Elsevier Applied Science.

and Σ means the sum of, E = the expected (theoretical) value, and O = observed value.

A simple method to assess conformity with a Poisson distribution, Fisher's Index of Dispersion test,[18] compares the actual and theoretical variances directly. An estimate of sample variance (s^2) is determined as the weighted mean of the sum of the squares of the difference ($x_n - \bar{x}$) of each individual result (x_n) from the mean result ($\bar{x}$); the "weighting" being introduced by dividing by the number of degrees of freedom (n–1) rather than the actual number of tests (n). The sample variance (s^2) is determined from the equation:

$$s^2 = \Sigma(x_n - \bar{x})^2 / (n-1)$$

The theoretical variance (σ^2) is given by the estimate of the mean $\bar{x}$ since, in a Poisson distribution, the population mean value (m) equals the population variance (σ^2). The Index of Dispersion (I)—the ratio of sample and theoretical variance—is determined from the equation:

$$I = \text{sample variance/theoretical variance}$$
$$= s^2 / \bar{x} = \Sigma(x_n - \bar{x})^2 / (n-1)\bar{x}$$

and is related to χ^2 by the expression: $\chi^2 = I\,(n-1)$

The significance of the extent to which I departs from unity can be determined from a table of χ^2 since $I\,(n-1)$ is approximated by χ^2 with ($n-1$) degrees of freedom, under the null hypothesis that the distribution does not diverge from Poisson. From tables of χ^2, or more approximately from Figure 60–5, agreement with a Poisson distribution is not disproved at the 95% probability level ($P > 0.05$) if the χ^2 value lies between the upper and lower significance levels for ($n-1$) degrees of freedom. If agreement is perfect, I = 1 and $\chi^2 = (n-1)$. More details of this and other tests for goodness of fit are given by Jarvis.[28]

60.1.2 Reproducibility and Precision of Microbiological Test Methods

The quality of data produced by any type of analysis is effectively measured in terms of the accuracy, repeatability, and reproducibility of the method. *Accuracy* is a measure of the quality of the test method (ie, of its ability to provide results equal to the true value). Deviations from the true value are referred to as method bias. *Repeatability* is the same as *random error* and is a measure of the difference between two single results found on identical material by one analyst using identical test conditions. The *repeatability value* (r_{95}) is the absolute value of the difference between two single results determined as above that will be found in 95% of analyses. *Reproducibility* is a measure of the difference between two single results obtained on identical material reported by two laboratories using identical test methods. The *reproducibility value* (R_{95}) is the absolute value of the difference in such interlaboratory results that will be found in 95% of tests. While it is quite normal for chemical and physical methods to cite repeatability and reproducibility parameters, they are rarely found in microbiological methods. However, interlaboratory trials of methodology such as those undertaken by the International Dairy Federation[37] are seeking to calculate both the interlaboratory and the intralaboratory errors and hence both the reproducibility and repeatability of the methods.

Intrinsic and extrinsic errors associated with serial dilution and colony count procedures include the accuracy of measuring the quantity of analytical sample, the accuracy of pipettes and pipetting, the accuracy of the diluent volumes dispensed, plating and incubation effects, colony counting and mathematical errors, and microbial distribution effects.[28] Assuming a random distribution of colonies in an agar plate, then the limiting precision (*Confidence Interval [CI]*) of the colony numbers can be derived from the actual count. As shown above, for data conforming to a Poisson distribution, the variance (s^2) is equal to the mean value ($\bar{x}$); hence:

$$s = \sqrt{\bar{x}}$$

By definition, approximately 95% of all replicate results will be expected to lie within the range $\bar{x} \pm 2s$. If the number of colonies counted totals 400, then the 95% precision of the colony count will range from $400 \pm 2 \times 20$ (ie, from 360 to 440). The precision of the count as a percent of the mean will be $\pm (40 \times 100)/400$ (ie, ± 10%) (Table 60–2). If the total number of colonies counted is 400, the limiting precision, at 95% probability, is approximately ± 10%, but if only 40 colonies are counted, the precision of the count reduces to ± 37% and at 10 colonies the precision is only ± 60%. However, if the colony distribution is not random, for instance if it shows evidence of contagion (*qv*), the 95% limiting precision (ie, the 95% confidence limits) will be much larger and significantly asymmetric.

The overall compound standard error of the mean count can be derived using the equation:

$$\textbf{Total SE}_{\text{mean}} = \pm\sqrt{[(A)^2 + (B)^2 + (C)^2 + \ldots (X)^2 + (Y)^2 + (Z)^2.]}$$

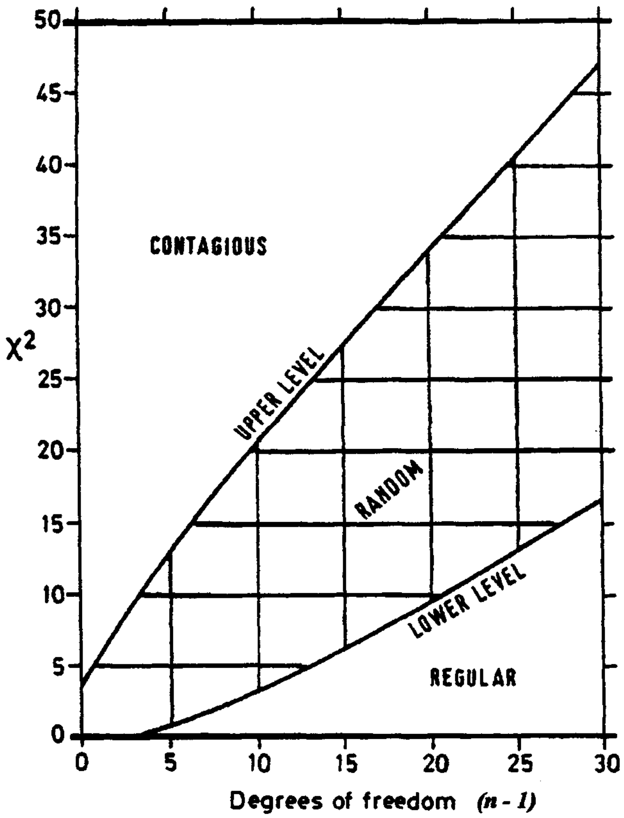


Figure 60–5 Goodness of Fit Test for Conformity with a Poisson Distribution. The χ^2 value is determined as described in the text for n -1 degrees of freedom, where n = the number of replicate counts made. The upper and lower limits for conformance with a Poisson distribution are set at p = 0.025 and p = 0.975, respectively. *Source:* Adapted with permission from J.M. Elliott, *Some Methods for the Statistical Analysis of Samples of Benthic Invertebrates*, 2nd ed., Freshwater Biological Association Scientific Publication No. 25, © 1977, Freshwater Biological Association.

---

where A = SE$_{\text{mean}}$ due to bacterial distribution, B = SE$_{\text{mean}}$ due to sampling errors, C = SE$_{\text{mean}}$ due to dilution errors, and.... X, Y, and Z refer to the errors associated with other aspects of the analysis (eg, counting).

Hence if the 95% limiting precision of sampling is ± 10%, the error associated with colony distribution is ± 30% and the error associated with dilution ± 10%, the overall precision of the count would be ± $\sqrt{[30^2 + 10^2 + 10^2]}$, ie, $\sqrt{[1100]}$ = ± 33.2%. Hence in 19 of 20 tests, a count of 45 colonies on the 10^{-6} dilution would indicate a microbial level of (45 ± 14) × 10^6 cfu ml^{-1} (ie, the count of 45 × 10^6 cfu would indicate a probable level of contamination within the range 30 × 10^6 to 60 × 10^6 cfu ml^{-1}; however, on average 1 in every 20 tests might be expected to give a true colony count outside that range. If the counts are transformed into their logarithms, the log cfu of 7.65 has a 95% CI ranging from 7.49 to 7.77. It should be noted that this range is now nonlinear as a result of the transformation. It is important to note, in the example above, that the potential error due to bacterial distribution (± 30%) is responsible for most of the combined error (± 33.2%), assuming reasonably good laboratory technique.[28]

Tests on replicate samples will each have their own limits of reproducibility based on the distribution of the mean counts of each replicate analysis. Experience suggests that on average, 95% of the mean log cfu counts will lie within ± 0.5 log units for a plate count on unstressed organisms, such as those from a broth culture. For plate counts on food materials, it can be expected that the range of counts lying within ± 2 standard deviations of the mean will often be much wider; for instance, replicate plate counts on bowl-chopped beef (Table 60–19) showed a mean log count of 6.48 with a variance of 0.075. This gives a standard deviation of the count of ± 0.274 log units such that approximately 95% of the counts would lie within ± 2 × 0.274 = ± 0.55 log units.

Provided that the individual log colony counts are distributed normally and that the means of replicate series of counts are themselves normally distributed, then on 95% of occasions the mean count indicates a true mean count lying within the range ± t × SE$_{\text{mean}}$, where t is a value, derived from tables of Student's t distribution, which is dependent on the required probability and the number of replicate tests (n). The SE$_{\text{mean}}$ is derived from the standard deviation (s) using the equation: SE$_{\text{mean}}$ = $s / \sqrt{n}$. In the example quoted above, for bowl-chopped thawed beef, the SE$_{\text{mean}}$ would be ± $0.274/\sqrt{20}$, ie, ± 0.06; and at 95% probability the value of t = 2.060, for n -1 (= 19) degrees of freedom. Hence, the 95% CI of the estimate of the population log mean count is given by 6.48 ± 0.06 × 2.06 (ie, 6.36 to 6.60). However, thawed beef (Table 60–19) had a mean log count of 5.93 with a variance of 0.334, such that 95% of log counts would be expected to lie within the range 5.93 ± 1.16 (ie, 4.77 to 7.09). The 95% CI around the mean is 5.93 ± 0.27, or a range from 5.67 to 6.20 log units. The literature contains examples[31] of much larger variances in log colony counts on foods with smaller numbers of replicate tests such that 95% CI

Table 60–2 Approximate 95% Confidence Limits for Numbers of Colonies Counted, Assuming Agreement with a Poisson Series

values, for mean log colony counts, in excess of ± 0.5 log units are commonplace. Any circumstances leading to a high variance (eg, nonrandom microbial distribution, sublethal damage, use of differential culture media) is likely to result in large CIs (ie, the mean values will have lower precision than the examples cited above). Such counts often will be used to make a decision as to the acceptability of a batch of product!

The CIs of most probable number (MPN) tests generally are wider than those obtained for colony count data; however, the extent of the CI will be dependent on a number of factors, including the dilution ratio and the number of replicate tests undertaken. For instance, from Table 60–3, a series of tests using 5 replicates at 10-fold serial dilutions of 1g, 0.1g, and 0.01g samples giving results of 3+, 2+, and 1+ would indicate an MPN of 1.7 organisms g^{-1} with a 95% CI of 0.7 to 3.9 organisms g^{-1}. It should be noted that this CI is asymmetrical about the MPN value determined. MPN counts can be made more accurate by using more replicates or by choosing a combination of replicates that will provide an estimate complying with a particular critical count level.[5] CIs for MPN data can be obtained from tables[15] or can be calculated from published equations.[12]

60.1.3 Acceptance Sampling by Assessment of Attributes or Variables

Whenever a decision is to be made about the acceptability of a product, it is necessary to first define the criteria against which that decision will be made. In the case of microbial contamination, the criteria may relate to numbers and/or types of organism that may pose an unacceptable risk to the well-being of the consumer or the quality of the product. For instance, the acceptability criteria for a product may include a standard plate count of aerobic mesophilic organisms, the absence of indicator organisms, and the absence of specific pathogens. Examples of such criteria are illustrated in Table 60–4 taken from The International Commission on Microbiological Specifications for Foods (ICMSF);[24] many other examples of microbiological criteria have been published,[2,3,4,13] although not all define proper sampling plans;[2,3,4] see also Chapter 65.

As an example of Attributes sampling, the ICMSF[24] plan for dried milk powder (Table 60–4) has limits for coliforms of $m = 10$ and $M = 100$. This is a three-class Attributes sampling plan (qv) where counts $\leq m$ are deemed to be acceptable, counts $> M$ are unacceptable, and counts $> m$ but $\leq M$ are deemed to be marginally acceptable. The defined limits m and M are therefore criteria against which decisions can be taken. The sampling plan also defines the number of sample units (n) to be tested (in this case $n = 5$) and provides a parameter (c) that defines the number of marginally acceptable sample results that can be tolerated ($c = 1$ in this case). The stringency of the sampling plan is defined principally by the values of n and c and is discussed in more detail below.

Other criteria for the dried milk powder include two-class plans for *Salmonella* spp. for various situa-

tions. In the case of product for high-risk situations, where the risk is likely to be increased following reconstitution of the dried milk, the plan requires $n = 60$, $c = 0$, and $m = 0$ with an analytical unit of 25g: in this instance, the acceptability criterion is that salmonellae should not be detected in 60 × 25g samples using a defined analytical method. The choice of analytical method is determined according to the purpose of the test and may include resuscitation stages. In these examples of microbiological Attributes sampling, decisions are based on the defined acceptability criteria and the standard statistical considerations applicable to any sampling protocol.

However, the concept of *Variables sampling* provides an alternative approach that uses more fully the data available from the analysis of replicate samples.[28,32] The data (eg, as cfu or log cfu g^{-1}) can be analyzed statistically to generate a value for the mean colony count (contamination level) together with a value for statistical variance around that mean value. Such data can then be compared with criteria defined in a different manner from those used in assessment of Attributes and use all the available data rather than making individual judgments on each test result. Variables sampling procedures more normally are used in chemical and physical analyses but have a role in modern food microbiology. A fuller exposition on Attributes and Variables sampling is given below (see Sections 60.2.2 and 60.2.3).

60.1.4 HACCP and Statistical Process Control

If the Hazard Analysis Critical Control Point System (HACCP), which is discussed elsewhere in this

book (Chapter 58), is to be effective, it is necessary to use appropriate procedures both to monitor and then to verify that a process is in control. The microbiological considerations will be explored in conjunction with the use of Statistical Process Control (SPC), a concept used to monitor production processes for key product parameters, which can also be applied to microbiological testing. Many data are never used effectively because once they have been filed, they are rarely seen again. In SPC, data are used on a continuous basis to assess whether unacceptable trends are developing over a period of time. The concept of SPC can be applied also to check that laboratory analyses are themselves "in control;" both aspects will be discussed in more detail later in this chapter in Section 60.4.

60.2 STATISTICAL BASIS OF SAMPLING PLANS

60.2.1 Characteristics of Statistical Distributions

Reference has been made previously (Section 60.1.1) to some of the different types of statistical frequency distributions, especially Poisson, binomial, negative binomial, and normal distributions and the relationships between them (Table 60–1, Figure 60–4). A frequency curve describes the probability that a particular event will occur in a given set of circumstances. For instance, if we flip a number of coins, we can predict the probability of getting a particular combination of heads and tails. Since the 2 sides of a coin are different, there is a 50% chance that when a single coin is spun, we will get either a head or a tail. If 2 coins are spun, the probabilities of getting 0, 1, or two heads are 25%, 50%, and 25%, respectively. Similarly, if we have 4 coins, the probabilities for obtaining 0, 1, 2, 3, or 4 heads are 6.75%, 25%, 37.5%, 25%, and 6.75% respectively; and so on for larger numbers of coins. The sum of all probabilities *must* equal 100% (ie, $P = 1$).

This is analogous to estimating the probability that a randomly drawn sample of n units will contain 1, 2, 3, ... n defective units at any given incidence of actual defective units in the population from which the samples were drawn. Mathematically, we can derive the probability (P_x) of obtaining any given number (x) of defective units out of a sample of n units, from the general equation for the binomial distribution:

$$P_{(x)} = \frac{n!\,p^x q^{(n-x)}}{x!(n-x)!}$$

where n = the number of sample units, x is the number of defective units, p is the true probability of occurrence of defective units in the lot, q is the true probability of occurrence of acceptable units in the lot, and ! means the "factorial value." That is, $n!$ means the multiple of: $\boldsymbol{n}\,(\boldsymbol{n}-1)\,(\boldsymbol{n}-2)\,(\boldsymbol{n}-3)\ldots 1$. By definition, $\boldsymbol{q} = (1-\boldsymbol{p})$.

Hence, for a lot containing 20% defective units ($p = 0.2$ and $q = 0.8$), the probability of detection of 1, 2, 3, or more defectives in a sample of size n can be calculated. The probability of occurrence of no defectives in a sample of 10 units, assuming always that the samples are fully representative of the lot and that the methodology is "perfect," is given by:

$$\boldsymbol{P}_{(x=0)} = 10!\,(0.2)^0(0.8)^{10} / 0!\,(10-0)! = 10!\,(0.8)^{10} / 10! = 0.8^{10} = 0.107$$

Similarly, the probability of occurrence of 1 defective in 10 sample units is given by :

$$\boldsymbol{P}_{(x=1)} = 10!\; 0.2^1\; 0.8^{(10-1)} / 1!\,(10-1)! = 0.268$$

and the probability of occurrence of 2 defectives in 10 sample units is given by:

$$\boldsymbol{P}_{(x=2)} = 10!\; 0.2^2\; 0.8^{(10-2)} / 2!\,(10-2)! = 0.3024$$

Since the proportion of acceptable samples (q) is given by ($1-p$), where p is the proportion of defective units, then the probability of occurrence ($P_{(x>0)}$) of 1 or more defective units in a sample can be derived from:

$$\boldsymbol{P}_{(x>0)} = \{\, 1-\boldsymbol{P}_{(x=0)} \}$$

Examples of the probability of occurrence of various levels of defective units in a sample size of 10 units for lots having different levels of incidence of actual defective units from 0.1% to 50% are shown in Table 60–5. Similarly, Table 60–6 illustrates the probability of occurrence of defective units according to sample size in lots having a 10% incidence of actual defective units.

From Table 60–5, it can be seen that the probability of occurrence (P_x) of 0 defectives in a sample of 10 units decreases from 0.99 when the true incidence of defectives in a lot is 0.1%, to 0.35 with 10% true defectives and 0.11 with 20% defectives. Conversely, the probability of occurrence of one or more defectives is 0.01, 0.09, 0.65, and 0.89 for lots having 0.1%, 1.0%, 10%, and 20%, respectively, if the sample consists of 10 units. Similarly, from Table 60–6, the probability of occurrence of one or more defective units from a lot having 10% true defectives increases with increasing sample size from 0.41 for 5 samples, to 0.65 for 10 samples, to 0.88 for 20 samples, and 1.00 for 100 samples. This means that unless the incidence of defectives is high, the likelihood of detecting defective materials in a lot is very low, unless large numbers of sample units are examined.

60.2.2 Statistical Aspects of Two-Class Attributes Sampling Plans

A two-class sampling plan defines the criteria for acceptance of a sample unit (eg, salmonellae not detected in 25g of product or standard plate count not greater than 10^6 cfu g^{-1}), the number of samples to be tested (*n*), and whether any defective (ie, nonacceptable) samples can be tolerated (designated *c*). In determining the sampling plan, due consideration must be given to the concepts of producer's risk and consumer's risk (see Appendix 60–A for definitions).

The data on the probability of acceptance of a lot containing defective units (Tables 60–5 and 60–6) can be presented as a series of cumulative probabilities in Operating Characteristics (OC) Curves (Figures 60–6 and 60–7). These illustrate the probabilities of acceptance, or rejection, of samples with particular levels of occurrence of defective sample units according to both the true incidence of defectives and the numbers of sample units tested. In Figure 60–6, two specific points are identified as the acceptance quality level (AQL) and the rejectable quality level (RQL) (also known as lot tolerance percent defectives; LTPD). The AQL indicates the probability of rejection of good lots. An acceptance parameter α (which should be close to zero: in the figure the value used was 0.05) is defined giving an AQL that is numerically equivalent to $1-\alpha$ (eg, 0.95 in Figure 60–6). For the illustrated data, the producer's risk would have a 95% chance of accepting lots with up to 9% defective units and a 5% chance of rejecting lots with < 9% defectives (ie, good product). At the other extreme, the parameter RQL defines consumer's risk, which is determined through a parameter β. In the example in Figure 60–6, β is set at 0.10, so that there would be a 10% chance that the accepted lots would contain 45% defective units and a 90% chance of rejecting lots with > 45% defective units. In setting a sampling plan, it is necessary to decide on the relative risks that should be applied to producer's and consumer's risk to establish values for α and β. Table 60–7 shows the proportion of defective units likely to be accepted or rejected at $P_a = 0.95$ and $P_r = 0.90$, respectively, for various values of *n* and *c*.

Figure 60–7 shows OC curves for various two-class Attributes plans with sample sizes of 5, 10, and 20 units. With a plan that allows no defective units (ie, $c = 0$) and examines 20 sample units (ie, $n = 20$),

Table 60–5 Probability of Occurrence of 0, 1, 2, ... 10 Defectives in 10 Sample Units from Lots with Different True Incidences of Defective Units (Based on Binomial Distribution)

< = less than 0.001

the probability of accepting a lot containing 10% defectives is about 0.12, whereas for a lot containing 1% defectives, the probability of acceptance is about 0.95. If the sample size is reduced to 10 units, the probability of accepting a lot with 10% defectives increases to 0.35. However, if the sampling plan permits the acceptance of defective units, then for a sample plan of $n = 10$, $c = 2$, the probability of accepting a lot with 10% defectives increases to 0.93; whereas a plan of $n = 5$, $c = 2$ would accept 10% defectives with a probability of 0.98. The discriminatory power of a sampling plan is therefore dependent on both the number of sample units tested, and whether it is permissible to accept one or more defective units in the sample units tested. The greater the number of sample units tested, the higher the stringency of the test; the lower the numbers tested and the acceptance of defective units reduces significantly the stringency of the plan. Table 60–8 compares the OC characteristics of several ICMSF two-class sampling plans.

It is reasonable to use a sampling plan based on the *binomial distribution* for relatively small numbers of samples provided that the lot size is large compared with the number of sample units taken for testing. However, when the number of sample units is large relative to the number of defectives (which is itself large relative to zero), it may be more useful to apply the normal distribution. If the incidence of sample defectives is very low, it may be more appropriate to derive the sampling statistics using the *Poisson distribution*. Details of the use of these distributions can be obtained from standard statistical texts;[8,35] recommended sampling plans have been published for single-, double-, and multiple-sampling schemes for various lot sizes up to and above 500,000 units.[9]

It should be recognized that OC curves also can be used to answer questions such as, "What is the probability of detecting randomly distributed salmonellae if *n* sample units are tested and the lot is likely to be contaminated at a maximum given level of salmonellae per kg?" *Assume that salmonellae are randomly distributed in a product (unlikely in practice), that 20 sample units are tested and that no salmonellae are detected in the tests.* Then, even though no salmonellae are found, Figure 60–7 shows that there is still a 95% chance that the product lot would be accepted with a true incidence of defective sample units (i.e., those containing salmonellae) of 0.26% (*ca* 1 in 400); similarly, there is a 50% chance that the lot would be accepted if the true incidence of defective sample units is 3.4% and a 10% chance that the lot would be accepted if the true incidence of defective sample units is 10.9%. A mathematical equation to derive maximum contamination levels from replicate tests is given later (see Section 60.5.2).

60.2.3 Double Sampling Plans

The stringency of a sampling plan can be increased by increasing the number of sample units (*n*) to be tested (eg, from 10 to 30 or more) and by decreasing the number of sample units of unacceptable quality (*c*), which it is possible to accept for the purpose of the plan. Rather than increasing the number of

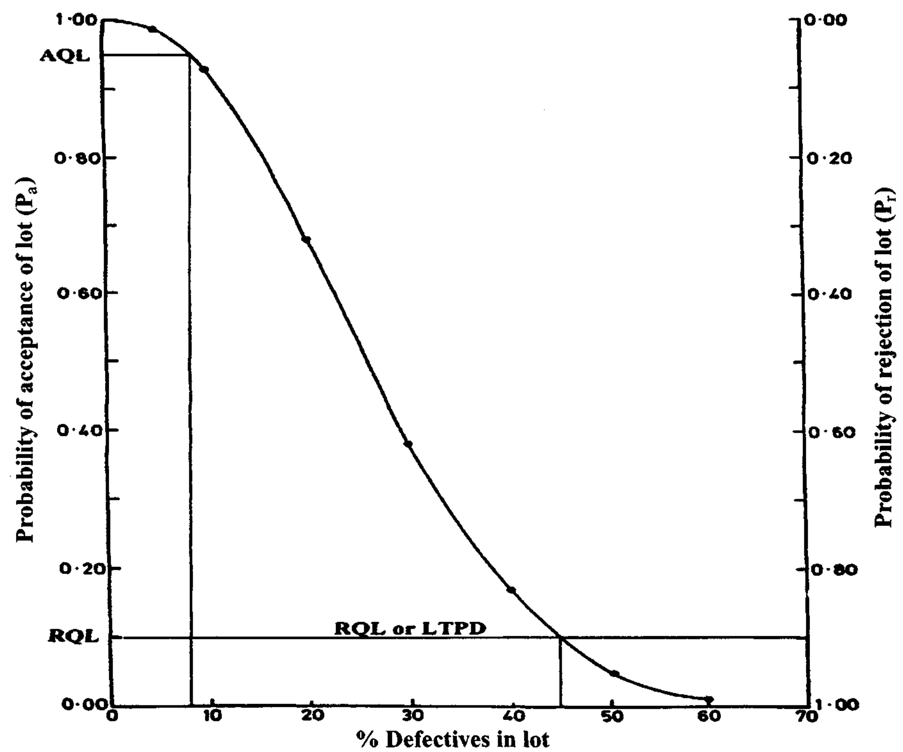

Figure 60–6 Operating Characteristics Curve Showing an Acceptable Quality Limit (AQL) of 9% Defective Units at P_a = 0.95 and a Rejectable Quality Limit (RQL, or LTPD) of 45% Defective Units at P_r = 0.90

---

sample units in totality, it is sometimes advocated that sample units should be drawn in two stages, such that there are two interlinked sampling plans, as illustrated below with reference to a lot having 5% defectives:

Stage 1 $n_1 = 20$, $c_{1a} = 0$, $c_{1b} = 1$	***Accept*** with 0 defective sample units ***Repeat*** analysis, on second set of sample units, if 1 defective sample unit ***Reject*** if > 1 defective sample unit
Stage 2 $n_2 = 20$, $c_2 = 0$	***Accept*** with 0 defective sample units only
Overall plan: $n = 40$, $c = 1$	***Accept*** if $\not>$ 1 defective sample unit is found in the first sample set and none in the second set.

In the first stage, if no defective is found in 20 samples from a lot having 5% actual defectives, the probability of accepting the lot ($P_{x<1}$) would be 0.36. However, if the lot was considered to be acceptable with 1 positive from the 20 samples tested in the first analysis, the probability of accepting the lot with 5% defects would rise to 0.74. In double sampling, the finding of a single defective in the first series would require a second set of 20 samples to be tested. Assuming that no positive was detected in this second series, then the lot would be accepted with P_a = 0.36 for the second series of 20 samples. Overall, it might be considered that the P_a for the lot could be determined from the quotient of the probabilities for accepting the two sets each of 20 samples, for example,

$$P_{x\le1} = P^{1}_{x\le1} \times P^{2}_{x\le0} = 0.74 \times 0.36 = 0.27.$$

This is not correct.

If the second set of samples is drawn, the sample plan must then be considered to be $n = 40$, $c = 1$ which, for a true incidence of 5% defective units, would accept the lot with a P_a = 0.40. Table 60–9 illustrates the difference in P_a values for some single- and double-sampling plans with AQLs ranging from 1.0 to 10.0.

Jarvis, Statistical Aspects of the Microbiological Analysis of Food, *Progress in Industrial Microbiology,* Vol. 21, © 1989, Elsevier Applied Science.

60.2.4 Statistical Aspects of Three-Class Attributes Sampling Plans

The introduction of three-class sampling plans was predicated on the recognition that quantitative estimation of microbial numbers by plate count and similar procedures has a relatively low accuracy and reproducibility. Factors affecting such data include not only technical inaccuracies involved in laboratory analysis but also the distribution of microorganisms in the original food sample.[28]

The three-class plan identifies the number of sample units (n) to be tested; a value (m) for acceptable colony counts, a value (M) for the upper limit of acceptability of counts, and a value (c) for the number of counts allowed to fall between m and M. Hence, a three-class plan might be:

$$n = 5 \quad c = 2 \quad m = 10^4\,g^{-1} \quad \text{and} \quad M = 10^5\,g^{-1}$$

This plan states that of five sample units tested, ideally all should give counts equal to or less than 10^4 cfu g^{-1} but not more than two sample units could have counts > 10^4 but ≤ 10^5 cfu g^{-1}; none must have counts > 10^5 cfu g^{-1}. However, whereas the two-class plan is normally based on the binomial distribution, the three-class plan is based on the trinomial distri-

Table 60–7 Incidence of Defective Units in a Lot That Would Have a 95% Chance of Acceptance (P_a) and a 90% Chance of Rejection (P_r) by Different Two-Class Sampling Plans Assuming All Replicate Tests Are Negative

	% Defectives in a Lot When			
	c = 0		*c = 1*

bution.[10] No colony count should exceed the upper level (M) so that the maximum acceptable number of defectives (c_M) is zero; but the sample plan will accept some marginal defectives (c_m) in the total number of samples tested (n). Hence the acceptable proportion of defective units is given by $p_M = 0$ and the acceptable proportion of marginal defective units is given by p_m. The probability for acceptance (P_a) of a lot of product can be derived from a simplification of the trinomial expansion, for values of i from 0 to c_m:

$$P_a = \sum_{i=0}^{c_m} \binom{n}{i} p_o^{n-i} p_m^i$$

where P_0 = proportion of good units, p_m = proportion of marginally defective units, n = number of sample units tested, and c_m = number of marginally defective units acceptable under the plan. This has the same form as that of a binomial expansion but it is not a general binomial since $p_0 + p_m \neq 1$. Values of P_a can be calculated from the equation:

$$P_a = \left\{ \sum_{i=0}^{c_m} \binom{n}{i} \left(\frac{p_0}{p_0+p_m}\right)^{n-i} \left(\frac{p_m}{p_0+p_m}\right)^{i} \right\} (p_0+p_m)^n$$

The expression inside the braces {} is a cumulative binomial term that can be read from standard tables of the binomial distribution.[36] The data in Table

* This value is not relevant because if the second set of samples is analyzed, the result must be calculated on the cumulative sample size (ie, first + second samples)

Source: Data from Sampling Procedures for Inspection by Attributes: Part 1. Specification for Sampling Plans Indexed by Acceptable Quality Level (AQL) for Lot-by-lot Inspection, BS6001: Part 1: 1972, amended April 1986, © 1986, British Standards Institute.

60–10 illustrate the effect of marginal defectives on the probability of acceptance of a lot having various proportions of defective and marginal defective units for sampling plans with $n = 10$ and $c_m = 0$ or $c_m = 2$. The data demonstrate that with a sampling plan of $c_m = 0$, the probability of accepting a lot (P_a) with 2% defective and 20% marginal defective units is 0.09, whereas for a plan with $c_m = 2$, the P_a is 0.55; similarly, if the lot contains 10% defective and 20% marginal defective units, $P_a = 0.04$ and 0.24 for $c_m = 0$ and $c_m = 2$, respectively.

The probabilities for acceptance based on a range of three-class plans for various levels of defective and marginally defective product are shown in Table 60–11. In the same way that an OC curve can be derived for a two-class plan, based on the expected incidence of defective product, an OC curve for a three-class plan can be derived based on the incidence of defective and marginally defective (or marginally acceptable) product. The OC curve for such a plan (Figure 60–8) is described by the geometric surface of a three-dimensional plot because for any value of defective units there will be a range of values for marginally defective samples.

60.2.5 The Statistical Basis of Variables Sampling Plans

A major disadvantage of any Attribute sampling scheme applied to a measurable parameter is that it makes no assumption about, nor allowance for, the distribution of measurable data associated with a lot. In the case of products for which defectives can be determined by inspection, this is of no consequence; however when results are based on the interpretation of quantitative data against predetermined criteria, which define whether the test data are or are not acceptable, there is an excessive risk of unfairly

Table 60–10 Probability of Acceptance for a Three-Class Plan with $n = 10$ and $c_M = 0$ According to the Proportions of Defective (q) and Marginally Defective (p_1) Units in a Lot and the Stringency of the Sampling Plan (Dependent on the Value of c_m)

rejecting otherwise acceptable lots. Indeed, Clark[11] showed that use of a three-class sampling plan with $n = 5$, $c = 1$ provides a 1 in 12 chance of rejecting a lot with 0% defectives and 10% marginal defectives—such a risk is unacceptable to a manufacturer and can result in wastage of much valuable foodstuff. Further examples are given in Table 60–11.

Analysis of much chemical and physical data is done on the basis of statistical analysis of the data and comparison of the mean and variance of the data with prescribed criteria. Relatively little attention has been paid to the application of Variables sampling schemes in applied microbiology. However, Kilsby and colleagues[30,32] showed that variables sampling can be used with quantitative microbiological data such as those derived from colony count procedures. It has been claimed[20] that use of variables sampling permits "better decision processes" with "economic benefits." Application of a Variables scheme does require statistical analysis of the data to determine the variance of the counts; and the data must conform to, or be capable of transformation to, a normal distribution. Because most colony count data conform approximately to a log-normal distribution, the raw data can be transformed simply by taking logarithms prior to statistical analysis.

As with Attributes sampling, it is necessary to define a critical level of microbial count (C) deemed to be the boundary between acceptable and unacceptable material; and to define a permissible percentage, d, of units in a lot that may be allowed to exceed this critical level to decide whether or not the lot is satisfactory. For data that conform to a normal distribution, the proportion (K) of values exceeding C depends solely on the population distribution and is given by:

$$(C - \mu) / \sigma = K$$

where μ = population mean and σ = population standard deviation. By reference to tables of the standardized normal deviate (eg, Table 1 of Pearson and Hartley[36]) the percentage of values beyond C can be derived for any value of K. For example, 20% of values beyond C would correspond to a value for K of 0.84, while 5% beyond C would be equivalent to K = 1.645. Conversely, the critical value of K (K_d) corresponding to d may be determined: for example, if d = 5%, $K_d = (C-\mu)/\sigma \leq 1.645$. Low values for K imply high percentages beyond C so that rejection may be warranted.

Because in most analytical situations neither μ nor σ will be known, they may be estimated from

Table 60–11 Probabilities of Acceptance (P_a) for Three-Class Attributes Sampling Plans When the Lot Examined Contains 5%, 20%, or 50% of Marginally Defective Sample Units with Various Proportions Exceeding M and Different Sizes (n) of Sample Units. The plans assume that marginally defective sample units can be accepted at various levels (ie, $c_m =$ 0, 1, 2, or 3) and that no defective units (ie, > M) are acceptable (c_M).

the sample data by the statistics $\bar{x}$ and s. Hence, an estimate of K ($\hat{K}$) is given by:

$$\hat{K} = (C - \bar{x})/s$$

The estimate $\hat{K}$ is as likely to exceed K_d as it is to fall below it. Therefore, an allowance for the lack of precision of $\hat{K}$ is derived by determining a value k, such that the probability of $\hat{K} < k$ is at least P when $\hat{K} < K_d$, and P is the desired lowest probability for rejection. Values for k may be calculated for specific circumstances[7,32] or may be obtained from standard tables (eg, Bowker and Goode, Table K).[8] For low values of n, the values of k derived by mathematical approximation[32] were found to be insufficiently precise, and revised values (Table 60–12) based on the central limit theory have been published.[32]

For an upper critical level of C, the acceptance criterion is given by: $\bar{x} + k_M s \leq C$ and the rejection criterion by: $\bar{x} + k_M s > C$. This is illustrated diagrammatically in Figure 60–9. Any value lying above the line for K is rejected, whereas a value lying below the line is accepted. The Variables sampling scheme can be applied to microbiological food control through the establishment of a safety critical value (C_M) and a Good Manufacturing Practice (GMP) critical value (C_m), in a manner analogous to the three-class Attributes plan.

The Variables scheme is used by calculating the mean and standard deviation of the log colony counts (log cfu) and determining values for k from Table 60–12A (safety/quality) or Table 60–12B (GMP limit). Suppose that two sets each of five sample units have been analyzed from two different lots of a product and that the absolute upper critical limit (C_M) is 7.0 (log cfu) and the GMP limit (C_m) is 6.0 (log cfu). Suppose also that the producer wishes to reject, with a 95% probability, any lot where the proportion (d) exceeding C_M is 5% or greater and to accept with a probability of 90% only those lots where the proportion exceeding C_m is less than 10%. Suppose that the mean ($\bar{x}$) log transformed colony counts of samples from lots A and B are 5.20 and 5.90 with standard deviation (s) of 0.25 and 0.24, respectively.

Then from Table 60–12A, the value of k_M is 4.2 and, from Table 60–12B, that of k_m is 0.68. On safety criteria, if $\bar{x} + 4.2\,s$ exceeds a value of 7.0 (ie, C_M), the lot must be rejected. For lot A, the derived value is given by $5.20 + (4.2 \times 0.25) = 5.20 + 1.05 = 6.25 < 7.0$;

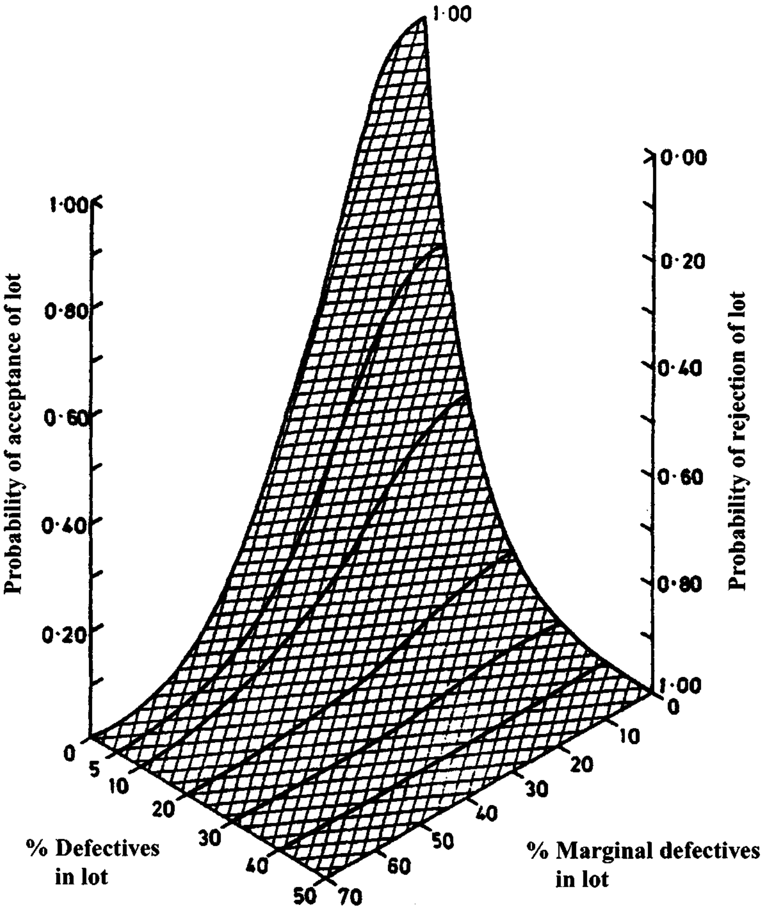

Figure 60–8 Operating Characteristics (OC) Curve Surface for a Three-class Sampling Plan with $n = 10$ and $c = 2$. *Source:* Reprinted with permission from B. Jarvis, Statistical Aspects of the Microbiological Analysis of Food, *Progress in Industrial Microbiology,* Vol. 21, p. 79, © 1989, Elsevier Applied Science.

hence, the lot is not rejected on the safety criteria. Similarly the derived value for lot B is given by 5.90 + (4.2 × 0.24) = 5.90 + 1.01 = 6.91 < 7.00 and the lot is (just) not rejected. From Table 60–12B, the GMP criteria state that $\bar{x} + 0.68\,s$ must not exceed a value of 6.0 (C_m) if the lot is to be accepted. For lot A, the derived value is given by 5.20 + (0.68 × 0.25) = 5.20 + 0.17 = 5.37 < 6.0 and the lot is accepted; but for Lot B, the derived value is given by 5.90 + (0.68 × 0.24) = 5.90 + 0.16 = 6.06 > 6.0 and the lot is not accepted. Hence, lot A would be accepted on both safety and GMP criteria; although lot B would not be accepted on the GMP criteria, it would be just acceptable on the safety criteria.

60.2.6 Variables or Attributes Sampling Plans?

There is no alternative option but to use a two-class Attributes sampling plan for assessment of product for the presence or absence of a specific group of organisms (eg, salmonellae). However, in any circumstance where quantitative data are obtained, the option exists to use either a three-class Attributes plan or a Variables sampling scheme. Is either better than the other?

In the case of the three-class plan, the results are attributed as being acceptable, marginally acceptable, or unacceptable by reference to the limits established for the plan (ie, *m* or *M*) and it is immedi-

ately obvious whether any count exceeds these limits. However, the distribution of organisms can affect the proportion of values likely to lie between *m* and *M* or to exceed M, such that the Attributes sampling scheme fails to give a constant probability of rejection as the proportion exceeding *m* or *M* increases (Table 60–13).[32]

The use of a Variables sampling plan is predicated on the supposition that the data, after transformation, will conform to a normal distribution. It is pos-

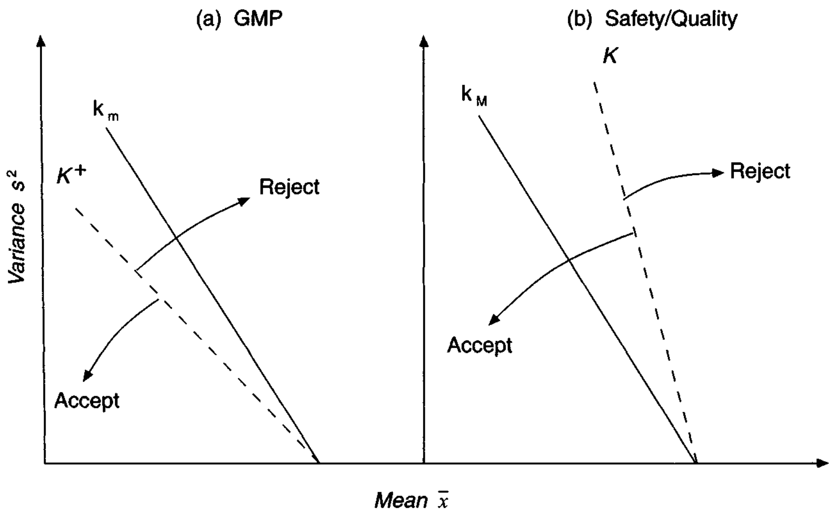

Figure 60–9 The Effect of the Standard Deviation in Microbial Counts in a Lot on the Response of a Standard Variables Scheme.[31] The lines k_m and k_M are derived from tabulated data (eg, Table 60–12) according to the number of replicate sample units allowed to exceed defined limits (C_m and C_M). The lines allow a fixed proportion of samples to exceed the limit and determine the proportion of defective product in the lot that will be rejected.

sible to check for normality using appropriate statistical techniques when the number of sample units tested is large (>100) but such tests cannot be applied if, as in most microbiological testing, the number of sampling units is small (often five or fewer replicate tests are carried out). If the data do not conform accurately to a normal distribution, then the use of Variables sampling plans may lead to wrong decisions resulting in excessive rejection or acceptance of a lot of product. Figure 60–10 illustrates a situation with two sets of data (A and B), each log-normally distributed and then the combined distribution, obtained by blending equal parts of the raw material (Figures 60–10A and 60–10B) and a ratio of 1 part A to 4 parts B (Figure 60–10B). Such an event could occur in industrial production where different batches of an ingredient may be used in the preparation of a single batch of food product; or in importation testing where more than one lot of product may be included in a single consignment. It is clear from Figure 60–10B, that when equal quantities of the ingredients are blended, the combined distribution of counts is no longer normally distributed, but the lack of normality is more difficult to observe when 1 part of A is blended with 4 parts of B because, in this case, only a small degree of skew occurs. To test for nonnormality requires application of an effective test, but the only reliable statistical procedures to make this test require a large number of data points to be available.

60.3 CHOICE OF SAMPLING PLANS

Effective sampling is based on the presumption that all sample units are drawn randomly from a lot, so that the quality of any one sample unit is typical of, and neither better nor worse than, the population from which it is drawn. It is therefore important to draw sample units to conform with the requirements of a sampling plan without introducing any bias in the selection of samples. While there is no guarantee that the quality of sample units drawn randomly from a lot will be typical of that lot, at least no bias will have been introduced in the choice of sample units.

The simplest method is to allocate a number to each unit in the lot and then to determine random numbers from a random number table[19] or generated by computer. In practice, this approach is rarely possible when a lot consists of large quantities of product produced under modern manufacturing conditions or held in the hold of a ship. It is easier to use a random number sampling scheme during manufacture when sample units can be withdrawn throughout the production process, but even then it may be almost impossible to ensure that a specific sample is

taken rather than an adjacent sample. Bulk liquid and granular products can be sampled using either a discontinuous or continuous sampling system (qv) or on a random time basis. However, once a product has been put into its primary packaging, then multipacked into cases and palletized, the application of totally unbiased random sampling procedures becomes almost impossible in practice. Several approaches to modifying the ideal scheme are described below. One approach is to deliberately stratify the lot to permit sample units to be withdrawn from each of a given number of different strata (eg, cases, pallets, containers, ship's holds). The objective is to provide an equal opportunity for sample units from different strata to be in the total strata.

60.3.1 Multiple Sampling Schemes

These are primarily applied to materials packaged in definable unit portions. Each bulk unit (eg, a pallet of cases) is allocated a number and the requisite number of bulk sample units is drawn using random numbers. One or more individual sample units (eg, cases) is then drawn from each bulk unit, again using random numbers. In many circumstances, it may also be necessary to sample from the individual case, thus leading to sets of samples being drawn from each level of packaging (eg, pallets, cases, individual product units [eg, packages or bottles]). This is a practical approach to minimize bias when it is necessary to draw a number of random samples from a consignment consisting of a large single lot of product (eg, a day's production held in a warehouse). An example of a procedure for multiple sampling is given in Table 60–14, which illustrates the effects of the different sampling regimes on the probability of acceptance or rejection of a lot subjected to multiple sampling.[9] These data assume a lot consists of 1,400 sacks of product stacked on 70 pallets each of 20 sacks. Assuming that the AQL required is given by AQL = 4%, then using a single sampling plan based on a "normal" level of sampling (qv), it would be necessary to draw a total of 125 sample units, of which a maximum of 10 units could be accepted as being defective (ie, $n = 125$, $c = 10$). Such a scheme would accept 4.9% defectives at $P_a = 0.95$ and would reject 12.3% defectives at $P_r = 0.90$. However, for a similar AQL, a double-sampling scheme would require testing 5 randomly drawn sacks (out of 20) from each of 13 pallets, each selected randomly from the 70 pallets; 1 pallet could be accepted as a defective unit. Such a scheme would accept up to 2.8% defectives at $P_a = 0.95$ but would only reject at $P_r = 0.90$ if 37% of units were defective. Clearly, such a multiple-sampling scheme is less stringent than a

Figure 60-10 Non-normality of Distribution Data Arising from Combination of Two Sources of Raw Material, Each Log-Normally Distributed and Having Similar Variance

single-sampling scheme in rejecting unsatisfactory materials but is often a pragmatic solution to the problem of drawing samples from large lots.

60.3.2 Stratified Sampling Schemes

When a consignment of product consists of several identifiable lots of product, it is essential to sample each lot within the consignment individually. The sample units drawn from each lot within the consignment should then be treated individually; results from the individual lots should be pooled only if evidence of homogeneity is obtained in the individual sets of results.

60.3.3 Sampling Frames

Sometimes it is not possible to sample a whole lot or consignment because of problems of accessibility. Such a situation might arise with stacks of boxes or sacks within a warehouse or a ship's hold. In such a situation, sample units are drawn, as described above, from those parts of the lot that are accessible (this is referred to as the "frame"). The results of the analysis apply only to the frame, not to the whole lot or consignment. However, if several frames are tested and the results indicate homogeneity, it is a reasonable presumption that the results on the frames tested may be indicative of those that might have been obtained by random sampling of the entire consignment or lot.

60.3.4 Deliberate Sample Bias

One traditional approach to sampling in the food industry is to deliberately sample a production line at a time when a problem might be expected to occur. For instance, if a pasteurized liquid product is being "clean" filled, it is often normal practice to test the first bottles filled after plant cleaning to provide evidence that the plant was effectively cleaned. While this may have some practical benefits in identifying inadequate cleaning of the packaging machinery, the data merely provide a retrospective verification that all was or was not satisfactory. The data apply only to those first sample units and cannot be related to the production lot as a whole. With modern rapid methods for checking plant hygiene (eg, analysis of adenosine triphosphate [ATP] residues), there is really little justification for such an approach to be used.

60.3.5 Normal, Tightened, and Reduced Sampling Schemes

Various published schemes for Attributes sampling by inspection or examination recommend the establishment of a protocol that varies the intensity of sampling according to the expected risk.[9] It is recommended, for instance, that under routine manufacturing or surveillance conditions, a sampling scheme should be operated using a *Normal* level of sampling selected according to the lot size and the

required AQL. However, if the risk associated with a particular process, or a specific source of product, is considered to be low, then a *Reduced* level of sampling may be used until evidence suggests a need to reintroduce *Normal* sampling. Likewise, if evidence is found for an increased hazard, then a *Tightened* sampling scheme should be used. Specific rules have been established to enable a decision to be made to move from one category to another (eg, *Reduced* to *Tightened* sampling).[9]

Table 60–15 illustrates a set of Reduced, Normal, and Tightened sampling schemes. The table shows that the number of:

- sample units to be examined increases with increasing lot size (see also Table 60–6)
- sample units required for a Reduced sampling protocol is less than for Normal or Tightened sampling
- acceptable defective units varies according to the plan, being fewer for the tightened scheme than for the normal scheme.

A lot size of 3,201 to 10,000 units requires the examination of 80 sample units for both Normal and Tightened inspection but only 32 sample units for Reduced sampling. For Normal inspection, the lot would be accepted with an AQL of 4%, provided not more than 7 samples were found to be defective (ie, $n = 80$, $c = 7$), but for the Tightened inspection, the lot would be accepted only if not more than 5 sample units were defective (ie, $n = 80$, $c = 5$). By contrast, the Reduced sampling scheme accepts not more than 3 defectives from the 32 sample units examined (ie, $n = 32$, $c = 3$) and rejects the lot if 6 defectives are found. In this instance, the test would need to be repeated if more than 3 but fewer than 6 defective sample units were found.

Schemes of this sort are very useful when the level of sampling can be changed according to the perceived need. For instance, it is possible to identify a production line as operating under green, amber, or red status according to recent experience of plant hygiene, or final product quality. Clearly, it is necessary to adopt rules to change from one state to another according to the perceived trends in contamination.

A similar approach was taken by ICMSF[24] in its recommended sampling plans for a variety of foods according to the perceived hazard and intended use. Table 60–4 illustrates the ICMSF recommended sampling plans for salmonellae in dried milk where the plan to be chosen is dependent on whether the expected handling, storage, and use of the product will reduce, cause no change in, or increase the level

of concern. For use by a high-risk population, the recommended sampling plan requires testing of 60 sample units if the hazard is likely to increase (eg, as a result of holding the reconstituted product under unacceptable conditions before consumption). Only 15 sample units need to be tested if the level of concern is reduced (eg, by consumption immediately after reconstitution). In all cases, the sampling plans require rejection of the lot if salmonellae are detected in any sample unit.

60.4 STATISTICAL PROCESS CONTROL CHARTS

Traditionally, microbiological counts of viable aerobic organisms and/or specific groups of organisms (eg, coliforms or Enterobacteriaceae) or tests to detect the presence or absence of specific pathogens (eg, salmonellae) have been used in microbiological quality control procedures. The objective is to establish retrospectively whether an ingredient, a partly processed product, or a final product conforms with a predetermined specification. Products not conforming are considered to be outside specification, which might lead to product destruction, recall from the marketplace, or other consequence. Often the specifications are based on intuitive understanding of the significance of certain levels of microorganisms but are not necessarily related specifically to any assessment of producer's or consumer's risk. Often microbiological procedures used in industry are not based on properly evaluated microbiological criteria; therefore, decisions may often be based on analysis of a single sample unit, sometimes even without any replication of the microbiological test. The introduction of recommended microbiological criteria[24] has been helpful in increasing understanding of the importance of using effective sampling plans. Nonetheless, even today much microbiological testing in industry is carried out using inadequate sampling plans.

An important role for application of microbiological criteria is in verification, but not monitoring, of critical control points (CCPs) within an HACCP system. Microbiological criteria *cannot* be used to monitor CCPs because, by definition, monitoring implies a rapid evaluation that traditional microbiological test procedures cannot provide. However, traditional methods can provide valuable retrospective data to verify the correctness of decisions based on the automated monitoring of chemical and physical criteria or alternative biological procedures, such as analysis of plant hygiene swabs for ATP.

Unfortunately, having spent considerable amounts of money on technician time and laboratory media to generate microbiological data for quality control purposes, the data are often examined in a cursory manner and then filed for posterity. How much better it would be if the data were analyzed further to provide evidence of trends that may be occurring. Such trends can be helpful also in the laboratory to establish whether colony count or other laboratory procedures are in control (see Section 60.5.3).

60.4.1 Statistical Process Control (SPC)

Increasingly, industry is adopting automated monitoring and control of manufacturing processes; regrettably, it is not yet possible for microbiological procedures to be incorporated in a timely manner in such systems of SPC. However, critical control parameters such as are used in HACCP (eg, temperature, pressure, pH, viscosity) and some chemical parameters can be monitored in this manner. The basis of SPC is the continuous analysis of process parameters so that the data can be assessed against predetermined criteria by a process control computer system. Such criteria are determined by surveying a process operating GMP over time in order to generate parameters for the expected mean, median, range, and/or variance of the data analyzed. Data from analyses of continuous variables (eg, temperature, pressure) generally conform to a normal statistical distribution where 50% of the data lie on either side of the mean value although nonstandard distributions of data may be observed, which require transformation to "normalize" the data before analysis. Once the critical parameters have been determined, the control computer can be programmed to enable continuous monitoring of new process data against these criteria and to identify when a system starts to go out of control. Indeed, in some industries, the control computer can adjust process parameters to remedy any trend that is detected outside predetermined limits. More information on SPC can be found in standard texts.[6,35,41]

60.4.2 Statistical Control Charts

The basis of SPC is essentially the use of statistical control charts such as the Shewart and Cusum charts,[6] which have been used by industrial statisticians for many years. The objective is to use process control data to monitor trends against predetermined criteria. Figure 60–11 illustrates the elements of a Shewart control chart having as a baseline a standard variable (eg, mean, standard deviation, proportion) together with upper and lower control limits. Such a chart could be used for colony count, MPN, multitube presence or absence test data, or hygiene swab ATP levels. The baseline (control limit [CL]) of the chart might be the process average ($\bar{x}$), the standard deviation (s), the range (R), or individual data. Above and, in most circumstances also, below the CL are two parallel lines: the upper and lower control limits (UCL; LCL). To establish a control chart, a minimum of 20 sets, each of at least 5 sample units, of process samples are analyzed. The average and range are calculated for each set of sample units and tested for compliance with normality by plotting a histogram either of the average values or of the values after normalization (eg, by taking log values). Assuming that the data conform with normality, the overall process average ($\bar{\bar{x}}$) and the overall process range ($\bar{R}$) are calculated. These values then become the CL (CL_x and CL_R) for $\bar{x}$ and R charts, respectively:

$$\mathbf{CL_x = \bar{\bar{x}} = \sum \bar{x} / n \quad CL_R = \bar{R} = \sum R / n}$$

where $\bar{x}$ = sample average, R = sample range, and n = number of sample sets.

The UCL and LCL values are derived from the process average ($\bar{\bar{x}}$) and range $\bar{R}$:

$$\mathbf{UCL_x = \bar{\bar{x}} + k_1\bar{R} \qquad UCL_R = k_3\bar{R}}$$

$$\mathbf{LCL_x = \bar{\bar{x}} - k_1\bar{R} \qquad LCL_R = k_2\bar{R}}$$

where the constants (k_1, k_2, and k_3), set at ± 3 s, are obtained from tables and are dependent on the sample size (n) (see Table 60–16). It should be noted that R is used to estimate the standard deviation, that different values of k_2 and k_3 are used for the lower and upper limits for range charts to reflect the different mode of calculation, and that no LCL_R is established for small numbers of sample units (n).

The interpretation of data on Shewart control charts is well defined: there are six recognized indicators of lack of control. These are:

1. a single point outside the UCL and LCL values
2. seven consecutive points falling on one side of the center line
3. two or more points in a row falling close to the UCL or LCL
4. ten of 11 points on one side of the center line
5. a trend of seven or more points in a row upward or downward
6. cycling of points above and below the target line.

Further information and illustrated examples can be found in Beauregard, Mikulak, and Olson.[6]

A Cusum chart (Figure 60–12) operates on a similar basis but, instead of plotting the actual data, the cumulative sum of the deviation between individual data values (or mean values) and a reference value is plotted on a rolling basis. Cusum charts do not normally have control limits but instead have upper and lower cumulative signal values. Cusum chart masks can be used as aids to assess statistically whether there has been a change in the process, but are not recommended by Montgomery.[34]

Table 60–17 presents data on microbiological counts determined on a manufactured food product over a period of several weeks. The reference values used are the target log mean count ($\bar{\bar{x}}$; expected to be 3.0 [ie, 1000 cfu g^{-1}]) with an upper log colony count limit of 3.5 (~3100 cfu g^{-1}). Figure 60–13A illustrates the plot of the individual mean log counts ($\bar{x}$) against time. Two small trends can be seen on this graph (from day 7 and again from day 15), but the data do not demonstrate lack of control as defined above until day 23 when two values exceed the upper Cusum control limit. A plot of the cumulative differences [$\Sigma(\bar{x}_i - \bar{\bar{x}})$] on a Cusum chart (Figure 60–13B) demonstrates a continual and significant upward trend from day 8 until day 23. This graph makes the development of an adverse trend much clearer than that seen in Figure 60–13A.

Similarly, Figures 60–14A and B show the use of charts to monitor trends in plant hygiene determined by measurement of ATP levels on swabs taken from the mandrel of a milk filling machine after cleaning.[22] Because these data were obtained from single samples ($n = 1$), traditional data analysis systems (eg, Shewart charts) are not suitable. Hayes and colleagues[22] presented their analysis after square root transformation to normalize the raw data on the assumption that the occurrence of ATP on production plant follows a Poisson distribution. However, there is no necessity for this transformation, because residual ATP levels will not necessarily reflect microbial contamination but rather will be indicative of ATP arising from both food residues and microbial cells. Data obtained by replicate analyses of ATP on process plant generally follow a log-normal rather than a Poisson distribution (Lindhardt, personal communication). The data, transformed to show the

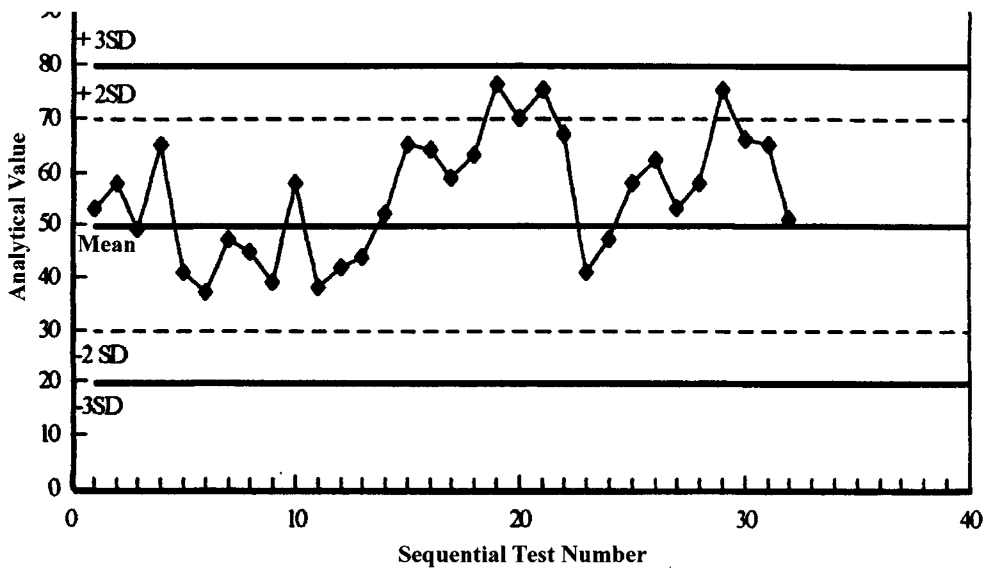

Figure 60–11 An Example of a Shewart Chart with Lines for the Process Mean (Control Limit), Warning (Upper and Lower Limits- - - - ± 2SD) and Action (Upper and Lower Control Limits— ± 3SD) levels. Superimposed on the chart are hypothetical data values.

deviation from the target value (assumed to be 50 relative light units [RLU], being a typical level for ATP on cleaned dairy plant) plotted against time (Figure 60–14A), show considerable day-to-day cycling of ATP levels—but no significant trends until day 73 when an unacceptable level of ATP (> 250 RLU) was determined. However, if the cumulative deviations in ATP levels are plotted as a Cusum chart (Figure 60–14B), significant trends can be seen from day 65, with other adverse trends having occurred also on days 23 to 30, 36 to 40, 46 to 48, and 84 to 90.

Loss of control is seen even more readily in Figure 60–14C, a single-sided Tabular Cusum plot.[29,34] The upper signal factor used (C_i^+) is derived mathematically as the greater value of zero or the calculated Cusum value from the equation:

$$C_i^+ = \max \left\| 0, x_i - (\mu_0 + K) + C_{i-1}^+ \right\|$$

where C_i^+ is the positive Tabular Cusum for the i^{th} data value (x_i); C_{i-1}^+ is the positive Tabular Cusum value for the previous data value (x_{i-1}); μ_0 is the target value and K is a reference value (sometimes

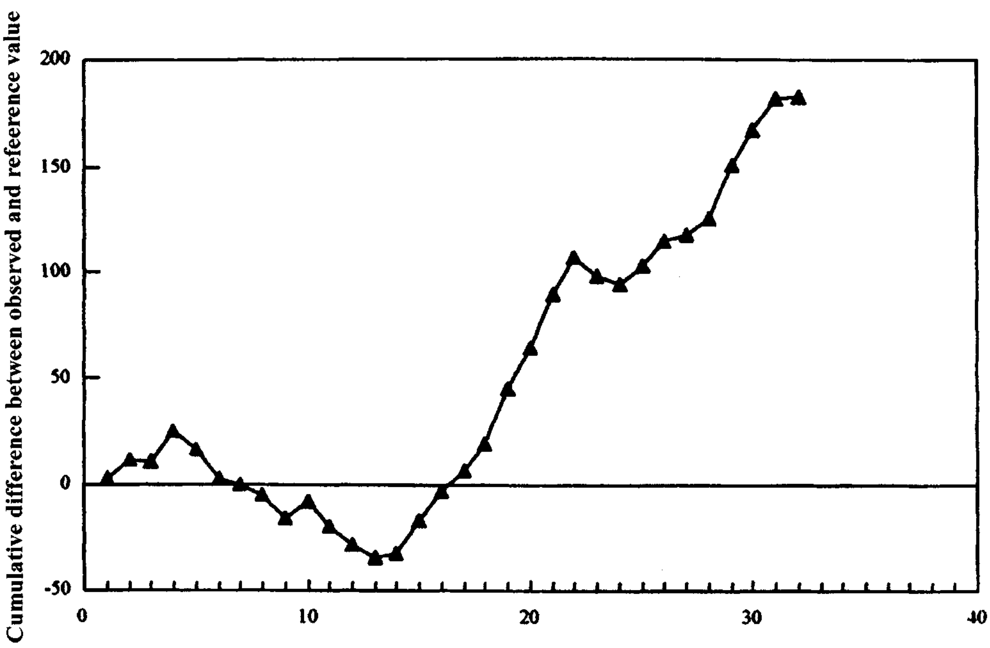

Figure 60–12 Cusum Chart. A plot of the cumulative sum of the differences between the actual data value and the process mean (target value) using data values from Figure 60–11.

called the allowance or the slack value). K is usually chosen as the value midway between the target (μ_0) and an "out of control limit value" (μ_1), that it is wished to detect as early as possible and is often 2, but may be up to 5, standard deviations above the target value. Thus $K = \frac{(\mu_1 - \mu_0)}{2}$. However, the Tabular Cusum can be applied only to data that conform to a normal distribution, so that microbial counts and ATP values must be normalized by taking logarithmic values of the data. Hence, as shown in Figure 60–14C, for which the target value (as log RLU) $\mu_0 = 1.7$, $s = \pm 0.2$ and the "out of control value" $(\mu_1) = \mu_0 + 2s = 1.7 + (2 \times 0.2) = 2.1$; then $K = (2.1 - 1.7)/2 = 1.9$. Figure 60–14C shows only those adverse trends in data that exceed the target value plus 1 standard deviation. Obviously, other target values and allowances could be used. For further information on preparation and use of Tabular Cusum, see Montgomery.[34]

The application of statistical analyses to routine data obtained in quality control analyses enables the information to be used positively to predict the development of adverse trends *before* a serious event occurs. Other types of control chart may also be useful in the assessment of data.[6,34,35,41]

60.4.3 Control of Microbiological Laboratory Data

Reference was made above (see Section 60.1.2) to the errors associated with microbiological testing. It is not appropriate in this chapter to consider the quality control of laboratory media, but it is important to draw attention to the need for quality assessment of laboratory media[40] (see also Chapter 62) and quality control of whole processes by the use of reference materials or foods. In considering the results of laboratory analyses, it is important to assess whether the laboratory analysis was in control by carrying out a simple statistical analysis of replicate data values.

Fisher and colleagues[18] were the first to demonstrate that abnormally large variations between replicate colony counts could be associated with factors causing contagious distribution of microorganisms and that subnormal variations (ie, regular distributions) are associated with culture media defects. As described above (see Section 60.1.1), a simple method to test whether a set of colony counts conforms with a Poisson distribution is to use Fisher's Index of Dispersion *(I)* test as a measure of the equality of variance and mean.

The statistical significance of the extent to which this ratio (*I*) departs from unity can be determined

from a table of χ^2 with (n –1) degrees of freedom or, more approximately, by comparison with a graph that relates the critical values for χ^2 against the number of replicate tests (Figure 60–5).

A χ^2 control chart can be used to test whether counts are in statistical control.[16] Because the critical value of the χ^2 test is dependent on the number of replicate colony counts, the procedure can be used only when at least duplicate counts are available at the same dilution level. An example of a χ^2 chart is shown in Figure 60–15. These data were derived from a series of colony counts of *Clostridium botulinum* and *C. perfringens*, using 20 replicate counts per test. Of the 32 sets of counts, one gave a χ^2 value marginally in excess of p = 0.025 and one fell below the value for p = 0.975. At the 5% level of significance, not more than 1 in 20 results should fall outside these limits if the hypothesis is correct that counts do not differ from a Poisson distribution. It may reasonably be concluded therefore that these counts essentially are in control. Obviously, these data are based on many more replicate counts than would normally be used in industrial practice, but even with duplicate counts useful information can be achieved by use of this procedure. A more detailed account of the application of these and other procedures has been published.[28]

60.5 SOME PRACTICAL ASPECTS OF SAMPLING AND ANALYSIS

The primary objective of sampling is to enable decisions to be made concerning the acceptability of goods based on assessment of either Attribute or Variable characteristics determined by inspection, examination, or analysis. Specific objectives will vary according to the circumstances and may include assessing the efficiency of process plant cleaning and sanitation, ensuring that a lot of manufactured product conforms with agreed criteria, checking incoming raw or partially processed materials, and assessing imported goods at the port of delivery. The implications of using sampling plans with a limited number of sample units compared with the higher level of sampling recommended by national and international standards organizations have been discussed above in relation to the degree of confidence in decisions based on the laboratory data. Of considerable importance is the recognition that the reproducibility and repeatability of laboratory data for microbiological purposes is inherently low due to the impact of microbial distribution on the results obtained. What can be done to improve reproducibility and repeatability in the laboratory?

60.5.1 Size and Comminution of Primary Samples

The distribution of microorganisms in food normally follows either a Poisson (random) or, more usually, a negative binomial (contagious) distribution that is approximated by a log-normal distribution.[28,30,31] The extent of the analytical variance of data obtained on replicate sample units affects the number of samples that need to be drawn to have a reasonable degree of confidence in the results (Table 60–18). If, for instance, the variance (s^2) of the distribution of microorganisms in a lot is 0.04 (s = ± 0.2 log units), it would be necessary to examine 60 replicate sample units to be 95% sure that the mean log count is within 90% of the true average count of microor-

Figure 60–13 Shewart and Cusum Charts for Colony Count Data Obtained from a Dairy Product (Using the Data in Table 60–17)

ganisms in that lot. However, if $s^2 = 0.25$ ($s = \pm 0.5$ log units), it would be necessary to examine 699 samples to have the same degree of confidence, although a lesser degree of confidence (ie, 90% sure of being within 50% of the true average count) could be obtained by testing 12 replicate sample units. Some values for microbial variance in food materials are shown in Table 60–19. Clearly, the higher the level of variance, the lower the degree of confidence that can be placed on the results.

The effect of microbial variance in a product can be minimized by increasing the analytical sample unit size. Table 60–19 illustrates the effects of increasing the size of the analytical sample unit on the variance of microbial counts obtained on replicate sample units taken from a frozen block of meat. Increasing the size of the analytical sample from 20g to 500g reduced the variance of counts from 0.274 to 0.026. Similarly, comminution of the meat after thawing by mincing and bowl chopping also reduced

the variance of counts from 0.334 to 0.075. Increasing the size of individual analytical samples reduces the intersample variation and ensures that each individual sample unit is more representative of the production lot than are smaller samples, provided that the entire analytical sample is macerated to produce the initial sample dilution. Comminution of the sample unit prior to taking the analytical sample unit will also give a more even distribution of microorganisms in the analytical sample and will therefore reduce intersample variation. Similar findings have been obtained on replicate counts on a diverse range of foods and other biological materials. The effects are particularly noticeable when examining dry particulates (eg, cereals, nuts, dried fruits) or multicomponent foods.

The data in Table 60–19 also show that the mean colony counts appear to increase as a consequence of both increasing sample size and comminution. This apparent increase is an artifact arising from use of the mean log colony count rather than the log of the average colony count; the latter is a measure of the true count.[31] An estimate of the average count $(\bar{A})$ is given by:

$$\bar{A} = \frac{1}{n} \sum_{i=1}^{n} x_i$$

where $x_1, x_2, x_3, x_4, \ldots\ldots x_i$ describes the level of organisms in each analytical subsample from sample 1 to sample *i*. Because the counts are log-normally distributed, the counts for each subsample will be distributed about the geometric average count or mean log count ($\bar{x}$),

$$\text{where} \qquad \bar{x} = \frac{1}{n} \sum_{i=1}^{n} (\log x_i)$$

The relationship between the mean log count and the log average has been defined[38] as:

$$\log \alpha = \mu + \ln 10\sigma^2 / 2$$

where σ^2 is the population variance of the log counts, log α is the log of the average count, μ is the population mean log count, and ln10 is the natural logarithm of 10 (2.3026). It is clear from this equation that the log average will always be greater than the mean log unless the variance is zero. Because, for any set of analytical data, s^2 is an estimate of σ^2 and $\bar{x}$ is an estimate of μ, then an estimate ($\bar{A}$) of the average count (α) can be derived by substituting s^2 and $\bar{x}$ in the equation above:

$$\log \bar{A} = \bar{x} + 2.3026 s^2 / 2 = \bar{x} + 1.1513 s^2$$

Because the log average count ($\bar{A}$) is the better measure of the true count, it can be concluded that when comparison is made with criteria, it is the log average count that should be used in order not to change the baseline as a result of examining samples of different size or from different stages of a production process—alternately, the sample size should be defined and kept constant and different criteria defined for each stage of a manufacturing process.

Table 60–19 Effect of Analytical Sample Unit Size and of Manufacturing Process on the Mean and Variance of Replicate Bacterial Colony Counts on Meat

60.5.2 Quantification of Data from Two-Class Sampling Plans

Calculation of Maximum Probable Level of Contamination. If salmonellae are present in a food in low numbers and are heterogeneously distributed, they are more likely to be detected if the variance is low, such as would be the case after bowl chopping of meat.[31] Hence, the effects of analytical sample unit size and pretreatment as described above will apply equally to the situation where salmonellae are sought using presence or absence tests. Habraken, Mossel, and van den Reek[21] and others have shown that salmonellae are not distributed randomly in dried milk-based products. Theoretical calculations, reinforced by examination of many tons of skim milk-powder products, showed that salmonellae occurred in nonrandomly distributed clusters. A similar situation also may occur, for instance, where postpasteurization contamination occurs. This creates enormous problems for drawing representative samples because the likelihood of detecting the presence of one or more clusters of salmonellae in a very large bulk of product is very low. The only realistic remedy is to examine a large number of individual analytical units and to ensure that the size of the analytical samples is sufficiently large. The sampling plan of Habraken et al.[21] recommends testing 300 × 2.5g sample units per lot. This is much more stringent than the most stringent of the ICMSF[24] sampling plans for dried milks (60 × 25g sample units per lot; Table 60–4) because the latter is based on the assumption that salmonellae are distributed randomly.

On the unlikely assumption that the incidence of defective units (eg, salmonellae) does occur randomly, it is possible to derive estimates of the probable maximum incidence or level of contamination for various probability levels (P). The equation, derived from the binomial distribution, assumes that organisms are distributed randomly, that n samples are examined, and that no positive results are obtained and is given by:

$$P = 1 - [1 - (d/100)]^n$$

where d = actual % incidence of defectives in a lot. This will be true provided that n is a small fraction of the total lot size. The equation may be rearranged to give the % defectives for a given probability (P) and number of sample units (n):

$$d = 100[1 - \sqrt[n]{(1-P)}]$$

For instance, if 30 samples were analyzed and all were found to be negative, then at a probability of P = 0.95, the calculated maximum incidence of contamination is given by

$$d = 100[1 - \sqrt[30]{(1-0.95)}] = 9.5\%$$

Assuming that each analytical sample weighs 25g, then the maximum likely level of contamination is given by (9.5/100) × (1000/25) = 3.8 salmonellae kg^{-1}. By contrast, if only 5 × 25g samples had been tested, again with negative results, the 95% probability of maximum contamination would have been 18 salmonellae kg^{-1}. Some examples of the effects of different sample unit size and number are given in Table 60–20.

Calculation of Most Probable Number from Presence or Absence Tests. If one or more positive results are obtained using a sample plan with $c = 0$, then the lot would be considered to have failed the test. However, a two-class sampling plan is essentially a series of replicate analyses that constitute an MPN test at a single inoculum level. It is possible, therefore, to generate an MPN from such data to give an indication of the probable incidence of contamination. The calculation uses the number of negative sample units at a single dilution level (ie, no viable organisms detected in the analytical sample) to derive the probability of occurrence of zero defects, so that:

$$P = z/n = e^{-vm}$$

where P = probability of occurrence of zero defects, v = the quantity of analytical sample unit tested in each replicate, z = the number of negative sample units, and n = the total number of sample units tested with a true density of m organisms per unit of sample tested. This can be rewritten as

$$m = -(1/v)\ln(z/n) = -(2.303/v)\log(z/n)$$

where ln and log are the logarithmic values to base e and base 10, respectively, and the other terms are given above.

Assuming that in a test of 30 × 25g replicate sample units, one positive result for salmonella is obtained, then the MPN of contamination can be derived as 1.36 salmonellae kg^{-1} with a 95% CI of <1 to 3.6 salmonellae kg^{-1}:

$$m = -(1000/25)\ln(29/30) = -40 \times -0.0339 = 1.356 \text{ salmonella kg}^{-1}$$

Similarly, two positive results would give an MPN of 2.76 salmonellae kg^{-1} (95% CI <1 to 6.1 salmonellae kg^{-1}). It should be noted that if no positive results had been obtained, then the MPN would be 0 salmonellae kg^{-1} with a maximum likely level of contami-

† Assumes one positive test out of *n* sample units; values derived using equation in Section 60.5.2.

nation, at 95% probability of 3.8 salmonellae kg^{-1}. Further examples for different sample numbers and sizes are shown in Table 60–20.

This procedure can be applied in many different circumstances. For instance, in an assessment of spoiled product, it can be useful to have an indication of the likely level of initial contamination. By counting the number of unspoiled sample units out of a large number of units examined (possibly the whole lot or a statistical sample of that lot), it is possible to derive an MPN for contamination of the lot using the proviso that each spoiled unit contained at least one viable organism. If this procedure is done on samples drawn from a range of lots manufactured on successive days or on different process lines, it is possible to assess the extent of contamination.

For instance, following the recall of a significant volume of bottled beverage due to reports of bursting bottles, it was possible to assess the extent of yeast contamination over a time continuum and then to relate this back to changes in manufacturing practices in the production plant concerned. It also permitted recalculation of the required process pasteurization conditions, based on the typical maximum level of yeast in the product prepasteurization, the known heat resistance of the organism, and the MPN of organisms in the packaged product. This eliminated pasteurization failure as a cause of the spoilage problem and focused attention on postpasteurization contamination. In this investigation, the typical level of contamination was found to be about one viable yeast cell per 10 liters of packaged product—a level that could not be detected with any reasonable confidence by microbiological sampling and testing of final product and reinforces the need for HACCP.

Implications of Sampling on the Laboratory Detection of Pathogens. Analysis for pathogens in food often requires a resuscitation, or pre-enrichment procedure, followed by elective or enrichment culture and finally detection of specific reactions on differential laboratory media (see Chapter 62). Individual colonies, presumptively identified as the organism sought, will then be selected for confirmation of identity using appropriate procedures. It is essential to recognize that such a sequential detection and isolation procedure involves sampling at each stage. For instance, unless sufficient time is allowed in pre-enrichment, the organism sought may not have recovered sufficiently to be detected and will not grow when transferred into the enrichment broth. Similarly, if only limited growth occurs in the enrichment culture, a loopful of culture removed to streak onto a differential medium may not contain the selected organism even if it is present at low levels in the enrichment culture. This would not be true if sufficient time had been allowed so that the enrichment culture contains a high proportion of the organism being sought. Picking of a limited number of colonies from a diagnostic medium for further examination also is influenced by statistical distribution unless a monoculture exists.[28]

60.5.3 Compositing of Samples

Laboratory protocols sometimes recommend that when many individual sample units are to be analyzed, some of the individual analytical units can be composited to reduce the total amount of testing to be carried out. Suppose that the ICMSF sampling plan[24] for salmonellae in skim milk powder is used with 60 × 25g sample units and that the sample units are composited to give the equivalent of 10 × 150g quantities. What will be the effect on the probability of detecting salmonellae? The probability of accepting a given incidence of defective units, if all test results are negative, is derived from the testing of 10 sample units each of 150g rather than 60 samples of 25g. From Table 60–6 it can be seen that if a lot has a true incidence of defectives of 10%, then $P_a = 0.35$ for $n = 10$, whereas for $n = 60$, $P_a = < 0.01$. Calculation of the maximum incidence of defectives at $P = 0.95$, using the equation in Section 60.5.2, shows that for $n = 10$, $d = 25.9\%$; for 150g samples, this is equivalent to a maximum of 1.7 salmonella kg^{-1}. For 60 samples each of 25g, $d = 4.9\%$, which is equivalent to 1.9 salmonellae kg^{-1}. Hence, there is a 35% chance of accepting a lot with greater than 1.7 salmonellae kg^{-1} if all tests are negative on 10 composite 150g samples, but there is less than 1% chance of accepting a lot with more than 1.9 salmonellae kg^{-1} if tests on 60 individual 25g samples are all negative. Clearly, testing of composite samples is much less discriminatory.

It is also important to recognize that if one or more of the composited sample units gives a positive test result, it is not possible to identify which of the 10 original sample units may have been contaminated. In practice, this may not be of importance if the result of a test is merely to accept or reject a lot; but if the incidence of positive sample units is required, then sample compositing will limit the availability of data. A compromise is to inoculate each sample unit individually into a pre-enrichment broth and then to composite appropriate quantities of the incubated pre-enrichment cultures at the time of inoculation of the enrichment medium. In this situation, any positive result can be checked by retesting the residual pre-enrichment cultures (provided they haven't been discarded).

60.5.4 Continuous Sampling

Devices for continuous removal of samples of solid or liquid foods are sometimes used to draw representative samples of material in process. One system for powdered milk products cited by Habraken et al.[21] enables a total of 300 × 2.5g samples to be drawn during the production of a lot. This was demonstrated to be a more efficient manner of monitoring for contamination than was testing a smaller number of larger samples drawn from the finished bulk product. However, such sampling devices are not normally suitable for testing lots of bulked or prepacked final product. Other forms of continuous sampling devices are used in the screening of consignments of peanuts and other bulk commodities for aflatoxin and other forms of contamination; they are normally applied during the mechanical transfer of product from a ship or other bulk container to a silo.

Sampling devices for liquid products take a continuous proportion of the liquid passing the sampling port, thereby yielding discrete (eg, timed) samples for analysis. Others pass a continuous stream of liquid through a captive membrane filter that can be removed manually at predetermined intervals for laboratory incubation and examination. However, such membrane samplers are frequently unsatisfactory in practice.

60.5.5 Environmental Sampling

The taking of environmental samples may be an important part of any regular production surveillance operation. Other than in relation to sampling plans for plant hygiene, for instance, based on swabbing clean, sanitized surfaces, most environmental sampling is predicated on random sampling of air and/or product residues from around the plant (eg, from air filters). Appropriate sampling plans can be defined on a plant-by-plant basis whereby a range of source materials identified in a HACCP study as being important are sampled on a regular basis for evidence of specific contamination.

60.6 CONCLUDING REMARKS

Sampling foods for compliance with criteria is done to enable decisions to be made as to the quality or acceptability of the product for use, sale, or consumption. Part of establishing the criteria is defining the required sampling plan; unfortunately, many published criteria[2–4] do not define sampling plans or are based on the use of only a single sample unit. The low level of repeatability and reproducibility of most microbiological methods means that little confidence can be placed in the results of such testing other than in relation to the specific sample unit analyzed.[30] Clearly, a single sample unit cannot be truly representative of a large product lot either in production conditions or in trade. Unfortunately, even the sample plans that are used frequently, such as those of ICMSF,[24] cannot provide a high degree of confidence in the data because the number of sample units specified in these sampling plans are significantly lower than the number regarded to be statistically necessary for rejection of defective material, and avoidance of rejection of sound materials, at a specified AQL level.[9]

Where the same product is made repeatedly under defined production conditions, the application of SPC systems adds considerable value to microbiological test data derived, for each production lot, from a limited number of sample units. However, such testing and analysis are retrospective and should be seen merely as an aid to safe food manufacture, which should be based on the principles of HACCP. Food products in trade cannot be examined effectively other than by end-product sampling, and for such products an effective sampling plan is essential, but even then no guarantee can ever be given that a product is safe or acceptable for consumption. Failure to detect organisms of public health significance may be due to inadequate sampling, imperfect methodology, and/or imperfect technique. Application of recommendations for safe food handling and control will always be more effective than excessive microbiological analysis of final products since quality and safety cannot be tested into a product.[1,13,23–27] Nonetheless, where testing is required, it must always be predicated on an understanding of those statistical factors that can affect both the analysis and the interpretation of the data.

Terms Used in Statistical Analysis and Sampling

The following definitions relating to statistical analysis and sampling for microbiological analysis are provided for ease of understanding of the text.

Acceptance sampling—Use of a predetermined sampling system to decide whether or not a "lot" meets defined criteria of acceptance. There are two types of acceptance sampling scheme: *Attributes sampling* and *Variables sampling.*

Acceptable Quality Limit (AQL)—A measure of the incidence of defective product that would normally be considered to be acceptable to a producer.

Analytical sample—see Sample

Attributes Sampling Plan—A sampling plan that considers the results of analysis purely in terms of defined attributes, which are graded as acceptable, marginally acceptable, or unacceptable according to the criteria of the plan.

Coefficient of variation (CV)—The ratio (as a %) of the standard deviation to mean value:

$$\mathrm{CV}(\%) = 100\frac{\sqrt{\text{variance}}}{\text{mean}} = 100\frac{\sqrt{s^2}}{\bar{x}}$$

Confidence interval (CI)—A measure of the spread of results about a mean value obtained (approximately) by multiplying the standard error of the mean by 2, for a 95% CI, or by 3, for a 99% CI. More accurate calculations of CIs are described in standard statistical texts.

Consignment—A quantity of product destined in commerce for delivery to a particular recipient, usually consisting of multiple units from one or more lots.

Consumer's risk—The probability that a lot will be accepted on the basis of analysis of sample units in accordance with a defined sampling plan, when in reality the lot as a whole is defective relative to the stated criteria of acceptability.

Defective—Not suitable for the purpose intended.

Frame—That portion of the lot from which the sample units are drawn; in practice, samples may sometimes be taken only from the accessible portion (or frame) of a lot.

Lot (or batch)—A quantity of product produced on a single occasion under a single set of production conditions and bearing a single identification number that relates to and defines the specific production run. The lot number might include data relating to the particular factory, production line, retort, date, or production time.

Lot Tolerance Percent Defective (LTPD)—Sometimes also called Rejectable Quality Limit (RQL), the LTPD is a measure of the incidence of defective product that is unacceptable to the producer.

Mean (arithmetic average) (usually designated $\bar{x}$, but sometimes designated m or λ)—The arithmetic mean, or average, value $\bar{x}$ obtained from a set of data values is calculated from the sum of the individual values (x) divided by the number of independent replicate tests (n):

$$\bar{x} = \left(\sum x_n\right)/n \text{ where } x_n = \text{individual values of } x \text{ from } n = 1 \text{ to } n$$

Mean log colony count (geometric average)($\bar{x}$)—Estimated by adding the logarithmic transformed counts (log x), dividing by the number of replicate counts (n), and then taking the antilog; or by taking the nth root of the product of the individual values (x) multiplied together, where n = the number of independent replicate tests.

$$\begin{aligned}\bar{x} &= \text{antilog}\left((\Sigma \log x_n)/n\right)\\ &= \text{antilog}\left((\log x_1 + \log x_2 + \log x_3 + \ldots\log x_n)/n\right)\\ &= \sqrt[n]{(x_1 \times x_2 \times x_3 \times \ldots x_n)}\end{aligned}$$

Log average colony count (log $\bar{A}$)—Estimated by taking the $\log_{10}$ of the sum of the individual counts divided by the number of replicate counts (n)

$$\log \bar{A} = \log((\textstyle\sum x_i)/n)$$

Operating characteristics (OC) curve—A statistically derived curve that relates the likelihood of accepting or rejecting a lot based on the expected incidence of defective units and the sampling plan used.

Population (microbiological)—The number of microorganisms, total or of defined species or group, dispersed within a defined quantity of food and detectable by defined methods.

Population (statistical)—The aggregate of units about which an inference is to be made from analytical results on a series of sample units; for practical purposes, the population may be taken to imply the total individual sample units within a lot.

Probability (P)—A measure of the likelihood that an event will occur; for instance, a probability of 95% (P = 0.95) indicates that an event would be expected to occur on average on 19 occasions out of 20, or conversely, that an event would be expected not to occur on average more than once in 20 occasions.

Probability of acceptance—The likelihood that a lot of known quality would be accepted on the basis of analysis in accordance with a defined sampling plan.

Producer's risk—The probability that a lot of acceptable quality will be rejected on the basis of analysis of sample units in accordance with a defined sampling plan.

Random sample of size n—A collection of n sample units obtained in such a way that every individual sample unit has an equal chance of selection, hence avoiding sampling bias.

Sample—The total number of individual sample units drawn at random from a lot that is to be tested in accordance with specific sampling plan and methods.

Sample (analytical)—The amount of material taken from a sample unit for analysis.

Sample unit—An individual portion or container of food taken as part of the sample and from which one or more analytical units are to be drawn for analysis.

Sampling plan—A statement of the criteria of acceptance to be applied to a lot based on examination of the required number of sample units by defined analytical methods.

Standard Deviation (s)—A measure of the spread of data relative to the mean. The term is obtained by taking the square root of the variance (s^2).

Stratification—A technique for dividing consignments into logical groupings such as can sizes, grades, boxes, or cases, that control known sources of variation. It may also be used to divide large lots or consignments into smaller groupings for purposes of sampling (see also *Frame*) and may be used deliberately when prior knowledge suggests that a lot or consignment is of uneven quality.

Variables Sampling Plan—A sampling plan in which the statistics (eg, mean and standard deviation) derived from analysis of sample units are used as criteria against which to assess the quality of the product (See also *Attributes Sampling Plan*).

Variance (s^2)—A measure of the spread of results in a set of n analyses; estimated by determining the sum of the squares of the difference between individual results (x_n) and the mean value ($\bar{x}$) and dividing by the number of degrees of freedom (n–1), ie:

$$s^2 = \frac{\Sigma(x_n - \bar{x})^2}{(n-1)}$$

61.1. PREPARATION OF SAMPLES FOR ANALYSIS

Because microorganisms are so small, they present very small analytical signals even when present in foods at levels (eg, 10^6 g^{-1}) typically acceptable for spoilage flora. At common levels of regulatory interest (1 cell 25 g^{-1}), whole single pathogen cells such as salmonellas represent only 10^{-13} of the sample, and probably only 10^{-18} to 10^{-19} of it if one is searching for a nucleotide sequence characterizing salmonellas. Thus, detecting and quantifying microorganisms in foods present challenges of varying severity. One may:

- extract whole target cells from the food and identify or quantify them by culturing and using their phenotypy such as serological or enzymological properties
- detect them directly in the food by analyses conferring on the target cells some property (eg, light emission, radioactivity) that is detectable against the background of the food
- extract a cell component (most probably DNA or RNA) to provide a relatively consistent base for analysis, regardless of the food/species starting point.

However, reliable microbe detection depends on moving the microbes from the food into the detection system. Even today there are no sampling methods capable of removing microbes quantitatively from foods. For spoilage flora, the best that can be hoped for is reproducible removal by the sampling method. Pathogens at low levels may exist in pores, cracks, biofilms, or other areas inaccessible to suspending procedures, and it is virtually essential to pre-enrich the whole sample to give them time to multiply and escape into a menstruum before attempting detection.

The mechanism by which microbes in foods or other substrates are detached by the sampling technique is essentially unknown and certainly much more complex than might appear at first sight. A puzzling feature of microbial detachment is that during sampling (rinsing, stomaching, or blending)

Acknowledgment: The author wishes to thank Dr A.C. Pinder of the Institute of Food Research, Norwich, UK, for writing the Section on Flow Cytometry.

the concentration of suspended microbes quickly reaches a plateau; however (where circumstances permit), repeating the process with a change of diluent liberates more microbes, frequently with barely reduced concentration. If the sampling process is repeated many times, the summed counts may yield a value much higher than suggested by a single processing,[28,130,134,191,193,226,260] and my unpublished observations.

Some authors have assumed that microbial release follows a first-order reaction, as though the microbes in suspension are able to inhibit the detachment of others; however, it is difficult to believe that the Law of Mass Action would have a significant effect on this type of behavior—other effects are surely more important. Shaking, swabbing, stomaching, or blending all cause a degree of tissue destruction, and even during the sampling process, microbes may reattach to newly exposed surfaces, or to components of the sampling device (for example, the swab fibers or the stomacher bag). Whatever the mechanism, one should not assume that the yield of microbes from any sampling technique (even blending) represents more than a small fraction of their actual level. This consideration is vitally important for the development of rapid pathogen detection methods because techniques are compared against traditional pre-enrichment methods, for which a single viable cell may eventually grow out into a broth and be detected, regardless of its state in the sample. If a rapid detection method requires preparation of a sample suspension, suspending less than all of the pathogen cells will clearly result in poor performance by the new method when cells are present at a low level.

Current microbe-suspending technologies (rinses, stomachers, blenders) produce large volumes of suspension (100 to 250 ml) to analyze sufficiently large samples of food. Yet powerful separation and identification techniques (immunomagnetic beads, flow cytometers) useful for ultrarapid analyses cannot handle more than a few milliliters of suspension. Reducing the primary suspension to a volume of a few milliliters or less is difficult because (except in very small number of circumstances): (1) it is likely to have a very variable composition in terms of the types and properties of the target microbe, of the types of particles suspended in it, or the degree of association of the target microbes with those particles, and (2) because the large volume of the suspension prevents the use of expensive reagents. There is an urgent need for new methods to generate primary suspensions and to purify and concentrate microbes in suspensions, both more suited to rapid detection procedures. In various parts of the world, work is in progress on the use of lectins, immunomagnetic particles, standing ultrasonic waves, dielectrophoresis, and other techniques to separate pathogens from foods.

The development of microbial dispersal methods predates food microbiology, although older procedures such as shaking samples with sand or even pouring molten agar over samples have largely disappeared. Methods producing an image of microbial contamination (eg, "agar contact" or RODAC*-type plates, sticky tapes) are useful but should not be used for estimating microbial numbers. For enumerative work, methods yielding reproducible and representative suspensions are essential. A short account of nonquantitative, semiquantitative, and quantitative methods of microbial detection follows.

61.1.1 Nonquantitative Methods That Yield Images of Microbial Contamination

The simple, inexpensive testing methods described in this section have a unique utility in monitoring hygiene or troubleshooting microbiological problems, but must not be regarded as providing quantitative information on microbial loads. Much evaluation work carried out in earlier years in hopes of using such methods as substitutes for excision and blending methods or swabbing showed very poor correlations. Colony counts on RODAC plates and dip slides are often less than 1% of the counts obtainable by a rigorous technique of microbial removal, dilution, and plating. Often it is only possible to infer that one surface is more contaminated than another, or that over time the level or type of contamination on a surface changes; however, virtually no other microbiological techniques have the ability to demonstrate, for example, a source of contamination such as a hairline crack in a piece of equipment—this is the real power of imaging techniques.

Agar contact plates, commonly known as RODAC or as Rosier-Pantaleon plates in France, are small (usually 65 mm diameter) sterile plastic dishes with arched lids, filled to the "convex meniscus" level with agar medium. They are simply opened, pressed carefully against the test surface, reclosed, and incubated. RODAC plates were introduced in 1964 for bacteriological monitoring in hospitals,[92] found widespread use in the food industry, and have been amply described and tested.[70,242,247] They are available prefilled with a variety of agar media through several suppliers or may be obtained empty for filling with special media. Their ease of use and the "contact prints" they show of contamination are well suited to the teaching of hygiene practices. Because they may be used onsite by relatively unskilled staff with little need for other equipment and returned to the laboratory for incubation, they are the ultimate in simplicity and convenience. The data must, however, be treated with the same caution as all methods in this section.

---

*RODAC, replicate organism direct agar contact.

Dip slides, also called AIPC (agar immersion, plating, and contact slides) by Mossel[161,162] are flexible plastic slides, covered on both sides with sterile agar media and enclosed in sterile, plastic tubes. They are obtainable custom-filled with specific culture media, frequently differing on the opposite sides. In addition to dipping into fluids, they can be pressed against surfaces in the manner of RODAC plates and are useful for microbiological testing of water, milk, foods, and manufacturing environments.[84,90,98,99,147,163]

Agar syringes and sausages are simple and inexpensive versions of agar-contact techniques, popular years ago because they permitted extensive monitoring of surfaces in food-processing facilities, but they have been replaced in plant environments by adenosine triphosphate (ATP) and other determinations. The agar sausage technique[246] used an agar-filled sausage skin, the exposed end of which was pressed against a test surface and then sliced off with a sterile knife and incubated in a petri dish. The agar syringe[197,267] is similar, except that agar was held in a large diameter syringe from which the end had been removed. Reduced moisture loss gave agar syringes a better shelf life than agar sausages. These are very underrated techniques, capable of providing much monitoring information around a plant at absolutely minimal cost.

Sticky tapes also can be used to remove microbial cells for direct microscopy or for plating and incubating in the manner of an agar contact technique. The techniques are not quantitative, but interesting specific effects occur; for example, viable amylolytic *Arthrobacter* spp. adhere to starch-based films[105] while dead bacteria or other species fail to do so.

61.1.2 Semiquantitative Methods

Swabs are essentially nondestructive to carcasses and equipment and yield minimal debris with the removed microbes, but their efficiency of microbe removal tends to be very unreproducible and usually well below the level needed in a quantitative sampling technique. Until recently, no swab techniques, except perhaps for the highly standardized Danish swab method[173] or the total object swab[160] yielded even reproducible fractions of the surface counts provided by more rigorous methods. In one of the most detailed and controlled studies on swabs,[106] a wet and dry swab method for carcasses and carcass meats gave summed counts from the two swabs ranging from 1% to 24% (average 10%) for fresh beef carcass, 27% to 52% (average 37%) for fresh mutton, 13% to 67% (average 44%) for fresh pork, and 25% to 89% (average 39%) for chilled pork belly, compared with counts from the excised, blended surface.

61.1.3 Methods for Quantitative Removal of Microbes

Improved Swabs. The limited release of foodborne microbes into suspension during sampling, and the possibility that newly exposed surfaces or the sampling device itself traps microbes liberated from foods, suggests that reproducibility problems of swabs stem from the high concentration of microbes built up at contact surfaces and inability to distribute them uniformly through even the small diluent volume held by the swab. The Rotorinser (Pro-Lab Diagnostics, Richmond Hill, Ontario, Canada) is an "improved swab." It holds a large volume of diluent (10 ml for a 50 cm^2 area) in a disposable, open-cell, urethane-foam cylinder that scrubs the test surface while compression and rotation of the cylinder pumps liquid repeatedly through the foam to bring microbes from the test surface into equilibrium with the diluent. The foam cylinder retains diluent when the process is stopped so that the instrument can be used on surfaces at any angle. In trials on pork skin and beef carcass surfaces, the Rotorinser removed a greater proportion of microbes than did excision followed by stomachering. For example, based on summed counts from double sampling (rotorinsing followed by stomachering, or stomachering followed by stomachering), the instrument gave removal efficiencies of 0.93 and 0.98 for 30- and 60-second operations, respectively, for pork, compared with 0.86 for a Stomacher.[225] On beef carcass tissue, the Rotorinser gave removal efficiencies of 0.74 to 0.91 for 30- and 60-second operations; however, stomachering was too destructive to the samples to permit a value to be obtained for comparison. The Rotorinser appears to provide a more representative analytical sample than swabbing or even excision and stomachering.

Spray Methods. Sprays also are relatively nondestructive and yield low debris levels. A spray gun that used air at a pressure of 35 to 207 kPa (5 to 30 psi) to spray diluent over the surface of samples, with washings being collected as they ran off, yielded bacteria counts as high as, or higher than, a blender.[34] Other workers have claimed various successes with similar techniques.[11,97,201] A "flush gun"[128,129] was capable of removing 50% of the surface bacteria count on pork or beef in 1 minute; with higher surface counts (above 5×10^7 cm^{-2}), a 90% efficiency was claimed. A portable instrument,[253] developed into the PASS (portable automatic spray system), is available from PBI International, Milan, Italy. It is limited to vertical or near-vertical surfaces.

Ultrasound and Vortex Stirring. Some early studies[103,149,189,195,196] indicated good removal of microbes from hard surfaces by insonation. For some food samples in glass tubes, agitated either in a vortex stirrer or suspended in an ultrasonic tank, removal of microbes compared well with conventional blending and yielded bacterial suspensions with a very low debris content.[218] For intact beef, peas, and green beans, total counts obtained by insonation were about 50% of those obtained by bladed blender. Insonation was less effective for prawns, which protected surfaces from the energy source (1.5 $\log_{10}$-cycles lower) and very poor with a compressed, comminuted meat (4 $\log_{10}$-cycles). Vortex stirring in glass test tubes was very effective, counts of total aerobes, *Staphylococcus aureus*, and *Escherichia coli* not differing significantly and being within ±25% of bladed blender counts for beef, sausage, chicken, prawns, cod, and green beans, and were 50% lower for peas and 80% lower for bacon.[218] Sonication conditions must be a compromise between effectiveness and lethality from cavitation. The small sample size and need to sterilize a container are problems for both techniques, and both seemed to have lapsed into obscurity.

Blenders and Stomachers. I am unable to find original articles on bladed or turreted blenders in food microbiology, but their use appears in many standard or official methods and they were long assumed to give "quantitative" suspensions of microbes from foods. Problems of noise, the need to clean and sterilize after use, overheating, and high levels of debris in suspensions have been problems. This led to development of the Stomacher, which processes samples in disposable plastic bags, massaging and crushing them under two paddles. It causes less tissue disruption than bladed blenders, and smaller temperature rises in the suspension.[219]

Through its convenience, the Stomacher replaced bladed blenders in many laboratories, but suspicion about its less destructive action led to many performance evaluations. The original evaluation[219] used peptone water diluent, but following further study,[221] addition of 1% Tween 80 surfactant usually is recommended to improve microbial yields from foods of moderate to high fat concentration. An exception is for materials such as butter when stomachering for membrane filtration. In the presence of surfactant, these foods emulsify and become unfilterable; in the absence of surfactant, they stick to the walls of the stomacher bag, leaving a clean suspension.[223,224]

In eight published studies, the Stomacher yielded about the same count as a bladed blender; in six there was no difference and in about 20 the count was slightly lower. The Stomacher gave higher counts than a blender for:

- poultry carcasses[1]
- cheese—and with no observable effect of citrate[7]
- aerobes and Gram-negative bacteria from frozen ground beef[111]
- in impedance measurements with meats[27]
- trichinella[138]
- hard and soft cheeses[166]
- meats, seafood, and cooked foods, although cheese, powdered egg, and milk gave lower counts[259]
- lung smears of *Pneumocystis carinii.*[252]

There were no significant differences between Stomachers and blenders for:

- casein[169]
- ground beef, celery, or wieners[211]
- counts of bacteria on chicken skin[248]
- *Trichinella*[250,251]
- high-fat dairy foods[254]
- (essentially identical) counts of *Listeria monocytogenes* from Colby cheese.[278]

The Stomacher gave slightly lower counts of

- coliforms and *Salmonella* in fatty foods[2]
- *Salmonella* from frog legs,[3] in a general comparison[2]
- in meat products and salads,[10,12,14] from raisins, hard cheese, and wheat grains and for molds in meats and sausages[21] for counts from human colon walls[43]

- *Bacillus cereus, Streptococcus fecalis, Yersinia enterocolitica*, and *Staphylococcus aureus*[50]
- *Listeria monocytogenes* in beef tissues, although Tween 80 increased the number of bacteria recovered from fat tissue,[51] in meats, with or without Tween 80[62]
- trichinae[79]
- *Clostridium perfringens*,[93] from chicken carcasses[121]
- aflatoxin in egg powder[138]
- from sputum[159]
- Enterobacteriaceae in chicken,[164] and in seafoods, pork, hams, and sausages.[168]

General reviews of Stomacher performance can be found in literature,[85–87,89,94,133,138,139,202,216,232] while others cover safety aspects,[39] improved bags with filters,[134] and control of foaming.[238]

A recent advancement over the paddle-type blender is called the Pulsifier (Microgen Bioproducts Ltd., Camberley, Surrey, UK). It accepts samples in disposable plastic bags; however, instead of kneading and crushing samples, it applies a combination of shock waves and intense agitation. Because microbes usually exist on surfaces or within easily accessible structures, "pulsification" efficiently disperses them. In a comparative trial[81] based on total aerobic counts from 96 samples of representative foods, the average ratio Pulsifier:Stomacher was 1.4:1. At very low count levels, total counts by Pulsifier were approximately twice those obtained by Stomacher, were significantly higher for samples with $<10^5$ cfu g^{-1}, not significantly different for samples with 10^5 to 10^7cfu g^{-1}, and slightly lower for levels above this. Except with precomminuted foods Pulsifier:Stomacher pulsified suspensions contain less food debris; for example, for celery and carrot total count ratios were 1.3:1 and 2.5:1, respectively, but pulsified suspensions were clear, while stomachered ones contained enough debris to interfere with pipetting.[81] Counts of coliforms (85 food samples) and *Escherichia coli* biotype 1 (36 food samples) by Pulsifier did not differ significantly from those by Stomacher.[222] All of the pulsified food samples filtered better through hydrophobic grid membrane filters (Section 61.1.4) than did stomachered ones, although the improvement varied with the food. For example, the ratio of filtration rates for Pulsifier:Stomacher varied from 12:1 and 10:1 for suspensions of beef liver and broccoli, respectively, to 1.4:1 and 1.3:1 for chili powder and feta cheese, respectively.[222] The improved filtration rates indicate a reduced level of suspended debris in suspensions prepared by pulsifier compared with paddle-type processors. This may prove beneficial for techniques in which interference by food components is a problem (eg, polymerase chain reactions [PCRs], or ATP bioluminescence); even its performance with total counts might reflect reduced interference and better visibility of colonies. Because the Pulsifier does not crush samples, hard objects (rice, bones, gravel) cause less bag-damage. A removable, transparent door allows the action to be viewed and improves accessibility for cleaning.

61.1.4 Microbial Separations As Part of Rapid Methods of Analysis

In the current race to develop faster screening methods, much attention is being paid to procedures for separating and concentrating microbial cells from the interfering components of food suspensions by means of physical or chemical methods, rather than waiting for multiplication to increase the microbial signal. Some of these techniques are well established; others are still in an experimental stage. The most pressing problem is that of initial treatment of the primary suspension. For rapid separation, it is essential for the separating or capturing agent to contact the target microbe quickly. For large volumes, the capturing agent must be inexpensive enough to be used in large amounts so that it can essentially fill the sample volume; this places severe limitations on the range of materials usable. Once the sample has been brought down to 1 ml or less, more sophisticated reagents can be considered. A theoretical treatment of microbial separations suggests that it is much more efficient (ie, faster) to separate the target microbe by using multiple steps of lesser efficiency, than a single step.[217]

Membrane Filtration Separations. This is a prime separation method, capable (not necessarily without difficulty) of separating microbial cells from food tissues, and of concentrating microbial cells for detection. Membrane filtration can lower limits of detection in direct microscopic methods by several orders of magnitude; for example, in the direct epifluorescent filter technique (DEFT). The DEFT-type procedure has been improved even further[257,258] for direct detection of *Escherichia coli* O157 in juice and meat at levels down to 10 cells g^{-1}. The DEFT, and a new instrument based on ATP bioluminescence (Microstar), are covered in more detail later in this chapter.

The success of membrane filter methods depends strongly on the filterability of food suspensions. Unprocessed foods (raw meats, fish, vegetables) generally yield suspensions that filter easily. With increasing levels of processing, addition of gums and fillers, food suspensions become less filterable, and dairy products often present problems. The problem usually is not difficult to overcome. Much work on the filtration of food suspensions was carried out during development of the hydrophobic grid membrane filter (ISO-GRID HGMF, QA LifeSciences Inc., San Diego, California), which is used for microbial enumeration and for detection of pathogens. Through its ability to "streamline" conventional incubation procedures on growth media, and its very wide (10^4:1) linear counting range, the HGMF provided a basis for many rapid counting and detection methods. At least seven of these have become official action procedures of the Association of Official Analytical Chemists International (AOAC), including counts of total aerobes, coliforms, fecal coliforms, *Escherichia coli*, a combined coliform/*E. coli* count, and yeasts and molds, together with detection procedures for *Salmonella* spp. and *Escherichia coli* O157:H7.[63–66,135,180,181,223]

To yield a linear count over many orders of magnitude, the HGMF exploits the most probable number (MPN) principle. Its grid of 1,600 (40 × 40) tiny grid-cells is equivalent to a tube-MPN assay of 1,600 tubes all at one dilution; the user does not attempt to count individual colonies, but rather, scores each grid-cell as positive or negative according to whether it contains any evidence of growth of the target organism. After obtaining the score (X), the MPN of colony forming units (growth units) that inoculated the HGMF is given by:

$$\mathbf{MPN = N \log_e ((N-X)/X)}$$

where N is the number of grid-cells (1,600 for the ISO-GRID HGMF). The MPN value can be much greater than N, since the "colony overlap" that prevents conventional agar plates from yielding accurate counts at much above 200 colonies, is accounted for by the logarithmic equation.[220] Automated counters, or microprocessor-assisted manual counters eliminate or simplify the counting step.

Although the HGMF relies on a relatively conventional incubation and growth of colonies, the MPN principle it exploits is now being used in a number of rapid or simplified counting procedures. For example, the Simplate (IDEXX Laboratories, Inc, Brantford, Connecticut) is based on passive distribution of a sample suspension into MPN wells, and the MicroStar system (Millipore Corporation, Bedford, Massachusetts) uses a hydrophobically partitioned membrane filter to apply the MPN system in an ATP bioluminescence-based rapid counting procedure (see Section 61.3.3).

For microscopy, where the ability of cells to multiply is not important, digestion with trypsin and Triton X-100 surfactant efficiently removes unwanted debris.[42,184,186,204,276] Where it is necessary to preserve the viability of cells, Triton X-100 should be avoided, in favor of Tween 80. Table 61–1 indicates the type of treatment to employ if a suspension is difficult to filter. The book by Sharpe and Peterkin[224] provides a more complete source of information on membrane filtration of foods.

Immunomagnetic Separations of Bacterial Cells and Toxins. Microbes can be caused to become ferromagnetic or paramagnetic by processes such as directly adsorbing submicron particles of magnetic iron oxides on their surfaces or treating them with Erbium (Er^{3+}) ions,[279] or precipitating ferromagnetic ions on their surfaces.[60] However, the most popular methods involve immobilizing microbes, in suspension, on tiny (2.8 to 4.5 μm) paramagnetic polystyrene beads (Dynabeads, Dynal, A/S, Oslo, Norway) or primed, silanized magnetic iron oxide particles (BioMag, Metachem Diagnostics Ltd., Piddington, Northants, UK) by means of lectins or, particularly, monoclonal antibodies. By using antibody-coated particles, other target species, such as microbial toxins, may also be made magnetic. The great attraction of immunomagnetic methods lies in the speed and simplicity with which the target species may then be separated by means of a powerful magnet (permanent- or electro-). Techniques may be as simple as collecting a pellet of magnetic cells, washing them by resuspending and recollecting, or more sophisticated processes such as thin-layer magnetophoresis.[177,207] The separated cells may be detected by simply plating them on normal growth media, by electrical impedance methods, or by PCR, where immunomagnetic separation can remove inhibitory materials,[75,175,270] enzyme-linked immunosorbent assay,[125] or other methods. Immunomagnetic methods can capture and detect dead microbes or those that are severely damaged and undetectable by standard culture techniques.[145]

In general, separation works best with fairly high levels of immunomagnetic particles. For salmonel-

Table 61–1 Enzyme Treatments To Increase the Filterability of Foods

Food	*Enzyme*
Skim milk	None
Raw milk	None
Butter and margarine	None
Other milks	Trypsin
Spray-dried milks	Trypsin
Cheeses	Trypsin
Spray-dried cheese powders	Cellulase or Protease
Sour cream	Diastase
Yogurt	Trypsin
Ice cream	
without stabilizers	Trypsin
containing gums	Hemicellulase
containing cellulose	Cellulase
Egg—liquid or powder	Trypsin
Raw or cooked meat or poultry	Trypsin
Shrimp	None
Oysters	Trypsin
Citrus juices	Pectinase
Fruit puree	Pectinase
Raw vegetables	None
Flour	None
Rice	None
Chocolate	Amylase
Breakfast cereals	Cellulase
Cake mixes	Amylase
Lecithin	Lecithinase
Food colorings	None
Gums	Hemicellulase
Infant formula	Trypsin
Sodium caseinate	Protease
Nut meats	None or Protease

Note: Suspensions of foods in this table frequently filter sufficiently well through membrane filters without treatment to permit common types of microbial count. In cases of difficulty, or where larger volumes are to be filtered to improve limits of detection, suspensions (1:10) are treated with 1% or 2% enzyme for 20 minutes at 35° C.

lae and *E. coli* O157:H7, particle concentrations as high as 10^6 to 10^7 ml^{-1} have been used.[76,230,264] Incubation periods of 10 to 60 minutes are required, and attachment increases with time. However, with unduly long incubation, nonspecific attachment and heavy contamination with nontarget microbes reduce the effectiveness of immunomagnetic beads as a selective analytical step. Surfactants such as Tween-20 or protamine reduce nonspecific attachment. Some limitation of immunomagnetic beads is found in the small volume analyzable because of the short range of a magnetic field, and a tendency for less-than-quantitative attachment even with great excesses of bead to target cell. Plate counts from immobilized microbes tend to be lower than the actual number of cells owing to a tendency for multiple attachment of cells; a common rule is that one colony may represent up to six target organisms.[230]

Interest in immunomagnetic beads has grown rapidly. A range of techniques and kits is now based on separating and concentrating suspended microbes, either directly from the initial suspension or after a short enrichment period to provide earlier detection.[30,31,44,113,140,141,230,231,256] Commercial magnetic particles are available primed with lectins or secondary antibodies to facilitate methodology. Among the methods developed are: detection of *E. coli* O157:H7 at a level of 1 cell ml^{-1} in meat after overnight enrichment;[172] microbiological confirmation of enterohemorrhagic *Escherichia coli* during an outbreak;[30,275] detection of salmonellae at levels of 10^2 cells g^{-1} in various foods.[231] Detection using anti-*Salmonella* Dynabeads was as good as three traditional procedures with food samples,[145] although an immunomagnetic bead method for detection of *Salmonella* in naturally contaminated feeds detected only 33% of positive samples, compared with up to 100% for four other methods.[72] K-serovars of *Vibrio parahemolyticus* were separated from foods, and *Vibrio hemolyticus* was identified in foods incriminated in food poisoning.[256] At least one commercial kit (VICAM Listertest, VICAM, Watertown, Massachusetts) is available for detecting or enumerating *Listeria monocytogenes.* For further information on use of immunomagnetic beads, see Chapter 63.

Centrifugation. Despite being a cumbersome step, centrifugation will probably continue to have a major role in microbial separation. For example, centrifugation at 2,000 g for 10 seconds prior to estimating biomass by ATP measurement removed virtually all meat particles without decrease in bacterial count.[235] Density gradient centrifugation can remove food debris without loss of bacterial count; a 15 minute method using colloidal silica clarified food suspensions,[8] and the automated density gradient apparatus of the Bactoscan instrument (see below) also allowed concentration of food-related microbes.[136] Sedimentation Field-Flow Fractionation separates pure bacterial cultures and is probably applicable to foods; cells are injected into an open, unpacked channel, first sedimented by a low (5 to 10 relative centrifugal field [RCF]) centrifugal field, then fractionated by the parabolic fluid-velocity field as diluent passes through the chamber.[215]

Standing Wave Ultrasound. Reflection of sound waves in a tube to yield standing waves causes suspended particles to concentrate at nodes, which can then be moved by varying the frequency.[37,91,158,269] It is tempting to think of detaching cells from a test surface, then moving them off to a place of collection by the same ultrasonic forces. Particle size, concentration, energy levels, and other factors affect efficiency and there has not yet been a practical application of the technique.

Dielectrophoresis. When an electric field is applied between plate and pin electrodes, slightly conducting particles suspended in liquid in the nonuniform field migrate to or from the pin electrode. The direction of movement depends on the relative conductivities of particle and liquid. Unlike electrophoresis, which requires direct current (DC), the dielectrophoresis effect occurs regardless of whether the electric field is alternating current (AC) or DC. Electrode assemblies are barely larger than the cells they are used with, and may be fabricated on silicon semiconductor chips. Complex electrode arrays can also rotate cells, and particles modify the applied fields, allowing electronic analysis of the situation.[82,102,182] While the small size of dielectrophoresis units is unlikely to allow their use for processing primary suspensions of foods, the ability to combine them with electronic signal processing and control suggests that they have a useful potential for separating microbes in food microbiological analysis.

Biphasic Partitioning. Bacteria, viruses, and other bodies partition themselves between the phases of aqueous biphasic systems (eg, of polysaccharide and gelatin mixtures), permitting some degree of separation.[17,142,150] Not only can *Salmonella* and *Escherichia coli* be separated, but so can rough/smooth mutants of *Salmonella typhimurium*.[236,237] Commercial applications in food microbiological analysis have not yet been described although biphasic separation is under evaluation by a number of groups.[178]

61.2 DETECTING MICROBIAL CELLS OR THEIR ACTIVITY

61.2.1 Microscopy

Older direct microscopic techniques suffered problems of poor limits of detection (10^7 cells g^{-1} or higher), distinguishing live cells from dead ones or from tissue organelles, and of relating microscopic counts to plate counts. A prime drawback has been that prolonged use of microscopes rapidly leads to fatigue and loss of accuracy. However, modern microscopic techniques can provide very rapid information on levels (even species) of microbes in foods, costs per test are low, automated instruments are appearing, and mounted preparations take up little space and may be stored for reference. Moreover, image analyzers improve continually in their performance and affordability and, through their ability to tirelessly examine large numbers of stained preparations, will eliminate some of the present drawbacks. At times, the information provided by microscopy may shed light on the history of a product in a manner that plate counts are incapable of. For example, although the plate count may become zero after a pasteurization step, the microscopic count may remain high because the enzymic activity that would normally destroy dead microbial cells also has ceased; a high count of dead microbial cells, however, can indicate that a food material was of general poor quality.

Even many years ago, procedures were developed to reduce drawbacks of direct microscopy; for example, examining microcolonies formed during short incubation periods,[80] or techniques in which microcolonies were detected by optical scanner[24] or by Coulter Counter.[25] The DEFT was a major advance, permitting concentration of organisms on membrane filters to improve limits of detection, and using a nuclear stain to distinguish live from dead organisms. Use of fluorescent antibodies to allow detection of specific foodborne microbes began with the Fluorescent Antibody (FA) Technique for salmonellae.[69] Although very useful in permitting screening for salmonellae in a much shorter time than previously possible, the method suffered from inadequacies of the antisera of the day (cross-reactivity, low sensitivity) and required a very precise technique and careful training to produce reliable results. For these reasons, it fell from popularity. An automated FA Technique actually was developed, probably several years prematurely;[165] however, labelled monoclonal antibodies have lent great power to DEFT-type techniques.

Direct Microscopic Counts. In these venerable yet still useful techniques, a known quantity of food is spread thinly over a defined area of a microscope slide or counting chamber, dried, fixed, defatted, and stained if necessary, and examined. Individual cells or clumps of cells are enumerated in sufficient microscopic fields to obtain a precise count. The commonest procedure, for the examination of milk, is ascribed to Breed.[26] The Howard mold count[101] requires a special counting chamber; it was developed for estimating rot in tomatoes but, like the Breed method, may be used under suitable conditions and with suitable precautions for other foods. Both procedures require considerable practice to achieve accurate results.

Direct Epifluorescent Filter Technique (DEFT). The DEFT enumerates viable and/or nonviable microbes. With a sensitivity limit of 6×10^3 bacteria ml^{-1} in milk and in other foods, it is essentially a technique for estimating spoilage flora, though there are instances where it may be possible to indicate potential hazards. Its great value is in yielding data in 25 to 30 minutes. It was developed for use with raw milk but now is used with many other foods; for example, for detection of molds in vegetable products[187,272] and evaluation of starter activity for fermented foods where rapid production of acid or other preservative agents is essential to prevent outgrowth of pathogens. The DEFT needs a minimum of equipment besides the epifluorescence microscope, and costs per sample are low. In its manual form it is labor intensive and involves prolonged microscopic work, but automated versions are now available.

The improved sensitivity results from concentration of cells on 0.2 μm membrane filters. Ability to distinguish live and dead bacteria results from staining with the nucleophilic fluorochrome acridine orange, which fluoresces at different colors in DNA and RNA during different phases of growth. Generally, viable cells fluoresce orange-red, while dead ones fluoresce green, although this is not an absolute rule. Food samples are digested with trypsin and Triton X-100 to improve their filterability, filtered through a "track-etched" membrane filter, stained with acridine orange, and sufficient fields must be examined under the epifluorescence microscope to give a reliable count. The DEFT requires only a moderate level of skill, but images must be interpreted with caution; for example, bacterial cells from heat-treated (blanched) products tend to retain their RNA, appearing to be "viable." The book by Pettipher[183] is the only one of its kind available, but a review[184] gives more up-to-date details.

A completely automated DEFT system (Cobra 2024, Biocom, Paris, France) is available with a sample throughput rate of 150 samples h^{-1}, and claimed repeatability better than the manual DEFT between 2×10^4 and 1×10^6 cfu ml^{-1}, with a lower counting limit better than 2×10^4 cfu ml^{-1}. The Cobra was basically intended for milk grading but gave good correlations with plate counts and manual DEFT counts for meats and fish.[188] Related automation includes an automated direct fluorescence microscope system (Autotrak) for continuous analysis of water and effluents,[212] which examines 140 specimens h^{-1}, providing results in 30 seconds, with good correlation coefficients for microbial counts in the range 10^4 to 10^8 cfu ml^{-1}.

The Bactoscan instruments automatically carry out an enumeration procedure rather similar to the DEFT. The method is an official procedure for obtaining data for "payment by quality" purposes in several European Union (EU) countries where the Class 1 limit for raw milk is 10^5 cfu ml^{-1}. In the Bactoscan III (Foss Electric, Hillerod, Denmark), milk samples are first digested to lyse somatic cells, then concentrated and separated by gradient centrifugation, rather than membrane filtration. After being stained with acridine orange, the sample is deposited on a rotating disk that is scanned by the computerized fluorescence microscope. A count takes approximately 7 minutes. Bactoscan counts tend to be higher than plate counts, partly because psychrotrophs are included.[45,153,199,243,244]

Related Direct Microscopic Techniques. The Viablue 2 procedure is similar to the DEFT procedure but uses the aniline blue stain Viablue 2 counterstained with rhodamine or Rose Bengal.[155] According to the authors, it gives a clear-cut differentiation between live and dead cells of bacteria and yeasts (dead cells fluoresce orange, viable cells green), allowing rapid determination of viable cell counts of bacterial isolates from milk, and *Listeria monocytogenes* isolated from soft cheese. Unlike acridine orange-based procedures, there was no reversal of staining with heat-killed cells.

Another membrane filter-based microscopic count (DINTS), described as suitable only for milks and derived from the DEFT, uses vital staining by means of 2-(p-iodophenyl)-3-(p-nitrophenyl)-5-phenyl tetrazolium chloride (INT), which produces crystals of black/purple formazan inside actively metabolizing cells.[18] Unlike DEFT, it requires only a standard microscope, plus the filtration accessories. DINTS requires only about 15 minutes, and the requirement that cells be actively metabolizing makes it more specific than DEFT.

Pathogen Detection by Direct Microscopy. *Escherichia coli* O157:H7 has been directly enumerated in milk and apple juice within 1 hour by an antibody-DEFT method.[257] After digestion with trypsin/Triton X-100 in the usual manner, the milk was stained with fluorescein-labelled anti-O157 polyclonal antibody; apple juice filtered adequately without digestion. Limits of detection in both cases were about 10^3 ml^{-1}. The antibody-DEFT technique also directly detected *Escherichia coli* O157 inoculated into beef at levels down to 16 cfu g^{-1};[258] a trypsin/Triton X-100 digest was passed through a 5 μm membrane prefilter prior to the 0.2 μm collection membrane. Detection of *E. coli* O157:H7 at this level would require two days or more by conventional methods, or slightly over one day by an immunostaining procedure on HGMFs.[245] While obviously capable of producing a more rapid result, detection at the lowest level by the antibody-DEFT method required the examination of 200 microscope fields.

Flow Cytometry. The technique of flow cytometry[157] owes its origins to classical microscopy, with the sample being viewed and assessed automatically. The basic principle is that the sample is forced to flow in a narrow, well-defined, liquid stream through a focused laser beam. As each organism passes through the beam, it is imaged onto photosensors, which measure optical changes. These changes are related to the size, shape, and fluorescence properties of the cell. Through the use of appropriate fluorescent labels, it is possible to measure total nucleic acid content, viability, surface antigens, or rRNA, for example. The power of the technique is derived from an ability to measure each cell one by one as it passes through the interrogating laser, and to measure a number of different parameters for each cell simultaneously by using multiple detectors. Owing to the cost and complexity of the instrumentation required, flow cytometry has not achieved the widespread application to food microbiology that it has to biomedicine; however, with the availability of cheaper bench-top instrumentation, such as the ChemFlow (Chemunex S.A., Maisons-Alfort, France) and the Bryte HS (BioRad, Hemel Hempstead, England), this situation is gradually changing.

The sample must be prepared in a liquid suspension, and prefiltering at around 50 μm is necessary to prevent large particulate matter causing flow problems. Typically, the sample flows through the cytometer at about 1 μl $second^{-1}$ and up to 5,000 cells $second^{-1}$ may be detected. However, the ultimate effectiveness of the system is limited not by optical and electronic considerations, but by sample preparation and the specificity of the fluorescent reagents used. Simple protocols with, for example, the nucleic acid stain ethidium bromide give a count of total number of organisms present in the sample. Although highly accurate for laboratory cultures, this method is less convincing when applied to meat or dairy samples. Flow cytometry has been successfully applied to the detection of spoilage organisms (yeasts) in soft drinks, where there exists a high background of other biological matter.[185] Through the use of fluorescently labelled monoclonal antibodies, it is possible to detect one or more target cell types within a mixed population. Clarke and Pinder[35] assayed two different salmonellae, even in the presence of a large excess of *Escherichia coli* cells, in samples of milk and eggs, down to a limit of about 10^3 cells ml^{-1}, with an assay time of 40 minutes. Fluorescently labelled oligonucleotides represent another form of highly specific probe suitable for flow cytometric analysis. They have been applied to microbial consortia in sewage, for example,[146] although their undoubted potential with food matrices has yet to be realized.

A number of protocols have been developed for the flow cytometric assessment of cell viability.[112] The Chemunex ChemChrome system is designed for use in industrial environments: a nonfluorescent precursor is cleaved by the action of intracellular enzymes in viable cells to release a fluorochrome, which is concentrated within the cells, provided their outer membranes are intact.[127] By combining ChemChrome with their monoclonal antibodies, and using three-color flow cytometric detection, Clarke and Pinder[36] improved their previously quoted detection limit by an order of magnitude. Also using ChemChrome, it is possible to detect so-called viable but nonculturable organisms; this technique was applied by Firth[74] to study *Vibrio vulnificus* in shellfish.

In its most elaborate form, flow cytometry combined with electrostatic cell sorting has been used to monitor *Cryptosporidium* oocysts in water.[265] Because there is potential for misidentification, the putative oocysts are automatically sorted onto a slide for confirmation of their identity by manual microscopy.

The use of flow cytometry combined with immunomagnetic separation of cells was shown to be a sensitive and rapid method for the detection of *E. coli* O157:H7.[214]

61.3 CHEMICAL AND BIOCHEMICAL TESTS

61.3.1 Bioluminescence

All animal, plant, and microbial cells contain the nucleotide phosphate ATP in relatively constant concentration. ATP can be measured within seconds at extremely low levels by a bioluminescent reaction in which oxidation of the substrate luciferin is catalysed by the enzyme luciferase. Originally, luciferin and luciferase were obtained from extracts of firefly lanterns;[154] both substances are now made from bioengineered organisms. The general procedure is to inject cellular extracts containing ATP into cuvettes containing luciferin and luciferase, with added magnesium ion at pH 7.4. Typically, the intensity of the luminescence rises to a maximum in milliseconds, then decays over a period of minutes. If luciferin and luciferase are present in excess, the maximum intensity of light emitted is proportional to ATP concentration. At least 90 ATP-based instruments of varying capability and price have been reviewed.[233,234]

Data for ATP content strictly relates to biomass, but can be related to numbers of target cells if the system has been previously calibrated for that organism. Microbes may be estimated through their ATP content; however, food analyses are complicated by the overwhelming excess of animal or plant tissue ATP, which decreases only slowly and incompletely when cells die.[216] The success of ATP determination for estimating bacterial numbers depends strongly on the efficiency of procedures used to separate bacteria from the food or destroy its intrinsic ATP before the assay. Although ATP data do not always correlate well with plate count, biomass is actually a better indicator of the stability of a product than is a count of colony forming units; for example, the total cellular mass of a *Streptococcus* chain better represents its metabolic potential than the single colony it produces on an agar plate.

Because they are present in greater numbers, ATP-based bioluminescence has found use for detection of spoilage organisms and monitoring starter cultures.[13,216,262,274] Until recently it had not had significant application to the detection of pathogens. Its greatest use is currently for measuring biofilms and food residues on surfaces,[15,126,213] and for this purpose portable instruments with disposable swab/reagent packs, which make them very easy to use, are now available for cleaning efficiency testing.

In addition to ATP-based bioluminescence tests, procedures based on nonluminescent microbes that were bioengineered to luminesce have been described. By recombinant DNA techniques the *lux* gene from a naturally luminescent bacterium, *Vibrio fischerii*, was inserted in phages or bacteria; the energy source is reduced flavin mononucleotide ($FMNH_2$) rather than ATP. Experiments such as insertion of the lux gene into P22 phage, which was then applied to *Salmonella typhimurium* culture, causing the phage-infected bacteria to become luminescent within 30 to 50 minutes have been reported.[239-241] The sensitivity and specificity of bacteria/phage reactions suggested a potential for shorter than normal enrichment times. Experiments in which luminescing bacteria became dark when injured, stressed, or killed quickly demonstrated the presence of antimicrobial residues or the activity of biocide preparations; for example, luminescent lactic bacteria quickly indicated the presence of antibiotics and bacteriophages in whole milk, a test relevant to monitoring starter activity;[240] however, no commercial applications of these techniques appear to have materialized.

61.3.2 Estimating Microbial Numbers by ATP Determination

Since even 10^6 bacteria g^{-1} represent less than one part per million of a food, the tissue ATP represents a massive excess requiring that special separation measures be used if the test is to be applicable to practical levels of bacteria. Separation methods tend to be based on differential filtrations, incubation with ATPases (apyrases), or combinations of these. The first step in differential filtration is to filter out food tissue cells because they are usually larger than microbial cells. Microbial cells are collected by filtration, washed to remove free ATP, and then their cell walls are perforated chemically to liberate the microbial ATP. In apyrase treatments, the enzyme acts on free ATP and is unable to attack ATP contained in the microbial cell; after destroying as much free ATP as possible, the microbial ATP is liberated and measured. While the theoretical limit of detection may be 1 to 10 cells in pure culture, it is difficult to reliably detect fewer than 10^5 g^{-1} of bacterial cells from most foods.

A typical method for estimating microbial numbers in fresh beef and chicken used a primary filter that removed 99.99% of nonmicrobial ATP, and a second that collected bacteria. The second filter was then treated with apyrase to remove further nonmicrobial ATP. Bacterial ATP was then extracted and measured. Quoted limits of detection were 5×10^4 cfu g^{-1} of meat sample, with bacterial levels predicted within ± 0.5 $\log_{10}$ of the actual aerobic plate count for more than 90% of samples tested.[137] Another procedure used for monitoring chicken quality in Hazard Analysis and Critical Control Points (HACCP) operations subjected chicken rinses to a coarse, then bacterial, filtration, followed by treatment with lipase. A limit of detection of 1×10^4 g^{-1} was reported, with a correlation coefficient of 0.85 against the standard plate count, and, at levels above 1×10^5 g^{-1} the ATP method accurately assigned 91% of samples to the correct quartile of a grading protocol.[15] Two methods for determining microbial loads from fecal contamination on carcasses are interesting. When carcass swabs were incubated with apyrase, total assay time was about 1 hour, but by using a filtration method assay time was reduced to about 5 minutes.[228] Correlation coefficients of 0.91 (beef) and 0.93 (pork) between microbial ATP and plate counts in processing plants, with limits of detection corresponding to $\log_{10}2.0$ (beef) and $\log_{10}3.2$ (pork) were reported.[228,229]

61.3.3 ATP Bioluminescence and Most Probable Number-Type Enumerations

Very recently, an instrument system was unveiled that potentially overcomes the tendency for poor correlation between ATP determinations and plate counts. The MicroStar Rapid Microbiology Detection System (Millipore Corporation, Bedford, Massachusetts) collects microbial cells on a hydrophobically partitioned membrane filter (HPMF) containing more than 600 compartments. The reader is referred to the HGMF (Section 61.1.4) for an explanation of how the MPN principle permits accurate counts over wider ranges than might be expected when one is familiar with counting colonies on plates or cells under a microscope. After filtration, the HPMF is sprayed with bioluminescence reagents and placed under an image intensifier, charge-coupled device (CCD) television camera, and image analyzer. The system "reads" the HPMF in approximately 2 minutes, and by analyzing the image can compute the number of microbial cells. The manufacturer claims that the system can detect large microbial cells, such as yeasts, directly; bacterial cells, being smaller sources of ATP, require incubation on growth media for a few hours in order to form microcolonies before being introduced to the bioluminescence reagents.

61.3.4 ATP Bioluminescence To Measure Surface Contamination and Cleaning

No matter how reliably cleaning and disinfecting solutions are made up, an important step to monitor during plant cleaning and sanitation is the thoroughness with which equipment surfaces have been cleaned. Dirt left on surfaces may harbor microbes that can recontaminate the product again as soon as the line is restarted. In particular, microbes in biofilms resist disinfectant solutions that kill unattached cells; thus, it is important to ensure that as much contamination as possible is removed from surfaces.

The great sensitivity of the luciferin-luciferase ATP bioluminescence reaction makes it an excellent way to detect unremoved material. The very problem that limits its use for enumerating microbes in foods (susceptibility to environmental ATP), becomes an advantage in monitoring surfaces in a HACCP operation. That is, although the ATP reading may not differentiate between microbes and food, the existence of a positive reading proves that the cleanup was not done properly (ie, the test is used to detect total ATP of both food and microbes). The test can be applied to a swab or other sample in 5 minutes; thus, a positive reading can be used to redirect the cleaning crew back to the area before processing is restarted.[16,126,213]

A number of instruments and kits specifically for hygiene monitoring are available. The instruments tend to be inexpensive, completely portable, have disposable sampling units containing swab, and all of the "chemistry" needed to buffer the test against interfering effects of sanitizers and other residues, then measure ATP after swabbing the test surface. Some instruments can be programmed to direct the user to critical control points or other points of interest, storing up to 5,000 test data that can then be downloaded to the laboratory computer.

61.3.5 Catalase Activity

While catalase activity measurements have been used for many years in monitoring the effectiveness of vegetable blanching processes,[5] and tests for catalase activity are commonly used during microbial identifications, several simple and rapid catalase tests are very useful in screening processes for incipient microbiological problems. At times it may be possible to calibrate the procedure in terms of microbial numbers; however, this is usually unnecessary.

For example, catalase activity in milk is cause for concern, regardless of whether it is due to microorganisms or leukocytes. A catalase test based on the time required for oxygen bubbles to refloat a sinking paper disk[32,273] is useful. The disk flotation method detects, in 2 to 3 minutes, for a few cents and with little skill requirement, gross microbiological problems in bulk milk or even the individual quarters of an udder. Reflotation time usually is checked visually, although an inexpensive instrument (Catalasemeter, Fisher Scientific, Pittsburgh, Pennsylvania) automates the timing if so desired. The test is useful for troubleshooting processing operations if spoilage microorganisms are catalase-positive; for example, catalase-positive contamination of vacuum-packed cooked turkey was detected at levels down to about 10^4 ml^{-1}.[52] At the lowest level, flotation took about 30 minutes. A simple test for field use described by the US Department of Agriculture for detection of flat-sour spoilage of canned corned beef simply required mixing 5 to 10 g of the product with 10 ml of 3% hydrogen peroxide solution and observing if bubbles formed.[48]

High levels of catalase activity are found in most tissues, and perhaps the most valuable use of catalase measurement resides not in tests of microbial presence but in monitoring critical control points of processes. Since catalase is destroyed rapidly above 65° C, any detectable catalase activity indicates lack of time/temperature control on, for example, a meat cooker. Chicken samples cooked to $\leq 69°$ C showed $\geq 99\%$ probability of positive catalase reaction, whereas samples cooked to endpoint temperature of 71° C had only a 3% probability of positive catalase reaction, and samples cooked to 72° C had no reaction.[4] A very simple field test based on formation of an oxygen foam when an undercooked meat sample is shaken with hydrogen peroxide and baby shampoo, requiring little skill and taking about 30 seconds, has been used for detection of underprocessing of roast beef.[67]

61.3.6 Limulus Amoebocyte Lysate Tests

Gram-negative bacteria, such as those primarily responsible for beef spoilage, are quickly detected in very small numbers by this test, which, though many years old, is still the simplest and most sensitive method available for detecting these organisms or, more strictly, the endotoxin (lipopolysaccharide) they produce. The reagent is derived from amoebocytes of the horseshoe crab *Limulus polyphemus*;[131] in the presence of purified bacterial endotoxins, it forms a gel similar to that from a positive coagulase test. As little as 0.03 ng ml^{-1} of purified endotoxin can be detected in 1 hour,[95] or as few as 50 Gram-negative cells.[38] Other workers have described limits of 0.05 ng endotoxin in 0.1 ml[132] and 0.5 ng in 0.1 ml,[271] and a variety of procedures.[107,114,115,205,277] These data are for relatively pure cultures, however, and in foods the limit is closer to 10^4 cells.

The basic gelation procedure requires minimal apparatus, and can be adapted to suit many foods; its cost compares favorably with that of making plate counts, but can be reduced still further if the test is miniaturized, for example, by using microtiter plates. In addition, since it detects both viable and nonviable organisms, and since the endotoxin survives common sterilizing processes, it affords some insight into the history of a product. Typically, 0.1 ml of suspected endotoxin solution or bacterial suspension in saline is mixed with 0.1 ml of *Limulus* amoebocyte lysate (LAL) in a test tube, allowed to stand 1 hour at 37° C, and inspected for gel formation. Various developments of the technique use turbidity or color reactions, and automated versions have been described.[114]

The test has been used successfully with ground beef,[107] sugar solutions,[95] and is probably useful for any products where the content of Gram-negative organisms is important. Detection limits range from 3.5×10^5 to 7.7×10^6 cells for various species isolated from meat, and within a closely defined situation, a reasonable correlation between LAL titer and numbers of Gram-negative organisms will probably be obtained. For example, LAL titers increased when ground beef was stored for up to 12 days at 5° C, and correlated well with counts of Gram-negative organisms.[107-111] False-positive results due to Gram-positive organisms or their products from a food should not be ruled out, and indiscriminate use of correlation factors to estimate bacterial loads is not recommended.

61.3.7 Determination of Microbial Metabolism

Electrical Impedance Measurement. An aqueous solution of neutral molecules conducts electricity no better than pure water. An ionic solution conducts electricity because ions move toward the electrodes in an applied electric field. A solution containing only large molecules such as carbohydrates and proteins has a low conductance, even if the solutes ionize, because macromolecules move slowly. Conductance (1/resistance) is a bulk property of the solution.

Adsorbed and immobilized molecules interacting with water molecules create electrical double layers at the electrode surfaces. Under an AC field, these electrical layers act as capacitors in series with the resistive bulk solution. The combined conductive and capacitative resistance is called the impedance. Through its capacitative component, impedance is frequency dependent. At low frequencies, an AC bridge measures mainly the capacitance, and at high frequencies, mainly the conductance; AC bridges operating at intermediate frequencies can measure both components simultaneously.

Microbial metabolism breaks down large molecules to small, mobile ions (H^+, acid anions), causing a progressive increase in the electrical conductance of the medium and changing electrode capacitance. Within limits, conductance change can be related to microbial concentration and the initial level of contamination. Within limits, capacitance change also reflects microbial number, though the effects are more complex. Selective detections, for example, of coliforms, yeasts, or *Salmonella* spp. can be made by varying the growth media and operating temperature.[55,57,73,88,167,209] Impedance or conductance measurement is now a popular means of estimating microbial contamination in foods or detecting pathogens. Several instrument systems are available, some measuring only conductance; others conductance and/or capacitance. Samples sizes range from 2 to 100 ml in reusable or disposable impedance cells, and the instruments handle at least 256 samples, are completely computer controlled, automatically interpret and record results, determine conformance with specifications, and can be connected into laboratory automation systems. Viable count estimations by impedance can often be made in 4 to 6 hours, there is no need to make dilutions, and optical clarity of suspensions is not important. While there are innumerable publications on applications of impedance, the book by Eden and Eden[57] is still the only comprehensive text on the subject.

Impedance changes due to bacteria only become detectable when cell concentrations reach 10^7 to 10^8 ml^{-1}; thus incubation is required for detection. The impedance detection time (IDT) reflects both the cells' initial number and their metabolic and multiplicative energies; thus, correlations with plate counts depend on the reproducibility of the microbial flora within a sample type. The technique is best used for "screening," or ascertaining whether or not samples fall within established specifications. From the regression line of IDT versus plate count for a specific sample type, and the coefficients of variation, a "gray zone" may be drawn around the maximum allowable plate count. Outside this zone, the impedance technique reliably indicates whether samples conform with the specification. Within the gray zone, one cannot be certain, and samples falling within it are re-analyzed by plate count. Because samples usually fall either well within or well outside a standard, only a minority of samples require re-analysis by plate count and overall analysis times and labor savings can be considerable.

Sterility testing of ultra-high temperature (UHT) dairy products, fruit juices and drinks, and aseptically packaged low-acid foods usually requires less than 48 hours.[41,208] The analysis usually involves pre-incubation of the sample (with or without added medium) at a temperature favorable for growth prior to transferring an aliquot to the impedance instrument for further incubation. Since impedance data reflect not only the count but the combined metabolic and multiplicative energy of the microorganisms, they can be better than plate counts at predicting shelf life. Impedance data predicted the shelf life of pasteurized milk better than did the Mosely test;[19,20,117] the technique requires a pre-incubation step at elevated temperature during which potential spoilage organisms multiply, followed by impedance monitoring in growth medium. A related use has been rapid detection of temperature abuse in broiler chickens.[206]

The conductance method for *Salmonella* based on the method of Easter and Gibson[56] was the first official method of the UK Ministry of Agriculture, Fisheries and Food,[192] and later achieved official action status of the Association of Official Analytical Chemists International.[5] It uses a nonselective preenrichment, followed by selective enrichment in media containing dimethylsulfoxide and mannitol during which the electrical detection is made. An alternative procedure[6] uses a bacteriophage specific for salmonellae. Other methods for detecting *Salmonella* have been developed based on media modifications,[170] or on impedance splitting (conductance and capacitance).[190] Direct impedance methods have been developed for other pathogens or indicator organisms; for example, for detection of *Staphylococcus aureus* in milk powders[192] or for fecal streptococci in milk powders.[167] Related uses include demonstration of antibiotic residue inhibition of lactic starters,[171,266] and mastitis in dairy herds.[119]

An interesting development is indirect conductimetry, where the electrodes are not immersed in the microbial growth medium but in a small vial of potassium hydroxide solution situated above it. Carbon dioxide evolved during metabolism reacts with the potassium hydroxide, reducing its conductance. The technique offers a more reliable means to detect yeasts whose products frequently do not increase conductance. It also permits high concentrations of salts to be used where selective media require them; detection of *Staphylococcus aureus, Listeria monocytogenes, Enterococcus faecalis, Bacillus subtilis, Escherichia coli, Pseudomonas aeruginosa, Aeromonas hydrophila,* and *Salmonella* spp. have been described.[22,54]

Dye Reduction, pH Indicators, Fluorogens, and Chromogens

Dye Reduction and pH Indicators. Like impedance measurement, any signal reflecting the combined multiplicative and metabolic activity of organisms can be expected to be better than a plate count as an indicator of the microbial potential for causing undesirable changes in the product. Metabolic data may permit better monitoring of raw material quality or be a better predictor of shelf life, allowing better control over the distributed product. Metabolic measurements may be made on any microbial property relevant to the problem (eg, dye reduction, impedance, production of acid, H_2S, color, toxin) if the instrumentation exists. At the same time, substances indicative of microbial metabolism are useful diagnostic agents in plate and MPN types of enumerations.

Many colorimetric indicators ("dyes") are available to detect reducing systems generated by microbial metabolism in a growth medium. Evaluation methods based on reduction of resazurin and other oxidation-reduction indicators by microbes were used for many years by the dairy industry, until wider use of refrigeration reduced levels of mesophilic bacteria, the principal microbial reducers of these dyes. Despite the fact that there may be large populations of mesophiles, dye reduction has been less extensively used with other types of foods, mainly because of problems with the variability of strains and species of microbes in their ability to change the E_h of their substrate, the existence of strong reducing systems in some foods, and difficulties of obtaining uniformly colored backgrounds against which the color of the indicator can be read. Nevertheless, the speed with which it is possible to demonstrate microbial contamination can be attractive enough to override these potential drawbacks, and interest in these techniques is again increasing.

Exploratory work on a range of foods was carried out as early as 1939,[194] and methods can be as simple as, for example, pressing dye-impregnated filter papers against the surface of meat patties;[61] however, instruments with automated detection and data handling are now available. These tend to be less expensive than instruments for impedance measurement and can also be used with pH indicator systems or any others indicative of microbial metabolism. The Omnispec system (Wescor Inc, Logan, Utah), based on reflectance colorimetry of litmus, resazurin, bromocresol purple, or triphenyltetrazolium chloride, has AOAC official action status for estimation of viable counts. Advantages claimed over impedance methods include lower instrument cost and reduced sensitivity to temperature fluctuations or electrical interference. The indications are that reflectance colorimetry has the same range of applications as impedance microbiology, such as estimation of total plate count, selective groups of organisms (eg, coliforms, yeasts and molds, *E. coli*), shelf life, and antibiotic sensitivity.[203]

Resazurin, which changes from blue to pink (resorufin) to colorless (hydroresorufin) during reduction is the most "sensitive" Redox indicator in common use, in that it is reduced most rapidly by microbial action; however, it must be used with caution because it may be reduced by other tissue systems. Methylene blue reduction (blue to colorless) provides better correlations with plate counts than does resazurin, and a range of tetrazolium salts (colorless to red or purple) has found varied uses. Among pH indicators, methyl red (4.8–6.0), bromocresol purple (5.2–6.8), bromothymol blue (6.0–7.6), and neutral red (6.8–8.0) have found greatest use for lactic or deaminating microbes.

A typical procedure based on resazurin reduction establishes the acceptability of a raw meat consignment at the loading dock better than organoleptic tests, if regulations permit trucks to be detained for 2 to 3 hours. Through the determination of regression lines fitting dye reduction times to plate counts, microbial loads of meats can be estimated with reasonable accuracy.[100] Meat sample suspensions are prepared by rinsing or by Stomacher, which causes minimal disruption of the meat tissue and release of reducing systems ("reductones") from meat; the test is not suitable for comminuted meats. Unsterilized skim milk powder is added to the suspension to provide a white background and to minimize coloration by meat; a Lovibond or similar comparator is satisfactory for measuring color changes. A similar procedure was used to demonstrate contamination in cooked or cured meats and aid in solving processing-associated problems, a time to end-point of 3 hours corresponded to a level of 10^6 bacteria g^{-1} in the meat, within about ±0.45 log-cycles.[53] A slightly different procedure, in which swabs of beef steaks were rinsed out and incubated with resazurin (no milk powder) yielded a correlation coefficient of 0.94 against the aerobic plate count, and permitted meat to be graded as containing $\geq 10^6$ cfu cm^{-2} in 2.2 to 2.3 hours.[263]

Methods based on the reduction of tetrazolium salts to colored formazans have been used for many years. Various tetrazolium salts have been used in, for example, detecting microbial contamination in fish,[227] but because many formazans are red, they are less easily distinguished from meat juices, and have been less useful with meats. The vital stain INT that produces black/purple formazan inside actively metabolizing cells has been used for rapid microscopic counts in milk.[18] An ingenious technique for visualizing the pattern of microbial contamination on cured or cooked meats helped locate the source of a processing problem. Fresh production samples of sliced ham were pre-incubated at 30° C to 37° C for various times, then sprayed with INT and incubated in sterile pouches at 37° C for 15 minutes. A pattern of curved parallel red/purple formazan lines developed on the ham slices and a minute nick (the seat of contamination) was discovered on the revolving blade of the slicing machine as it passed through the ham.[25]

Fluorogens and Chromogens. Many substances yielding colored or fluorescent products after reaction with microbial enzymes or other components of microbes are used in various aspects of analytical microbiology. For example, fluorogenic dyes such as 8-anilino-1-napthalene-sulphonic acid and acridine orange are used to detect DNA as in DEFT (above), and pH-fluorescent indicators such as acridine or 7-hydroxycoumarin are useful for detecting microbial activities. Many chromogenic substrates are phenol derivatives; for example, *o*- or *p*-nitrophenols or 5-bromo-4-chloro-3-indolyl compounds, and many fluorogenic substances, such as 4-methylumbelliferone, are derived from coumarin.[143] The hydrolysis of fluorescein diacetate by microbes has been shown to be useful for estimating the aerobic plate count of meat. Swabs of beef steaks were centrifuged, and the resuspended pellets incubated 3 hours at 25° C with the reagent before measuring absorbence of fluorescein at 490 mm. A correlation coefficient of 0.92 against the aerobic plate count was found, and meats with levels of 10^6 cfu cm^{-2} were graded satisfactorily.[263]

Derivatives of β-D-glucuronide or galactoside have found extensive uses in kits and other methods as detectors of glucuronidase or galactosidase activities in rapid tests for presence of coliforms or *Escherichia coli*. The fluorescence precursor 4-methylumbelliferyl-β-D-glucuronide (MUG), which is metabolized by glucuronidase-positive microbes to a fluorescent umbelliferone, has been particularly popular. For enumeration on plates or membrane filters, MUG is less convenient; the need to count colonies under ultraviolet (UV) light and a tendency for diffuse staining are problems. Glucuronidase substrates providing visible color changes and insoluble colored products are preferable. Compounds such as 5-bromo-4-chloro-3-indoxyl-β-D-glucuronide (BCIG, also called X-gluc) and indoxyl-β-D-glucuronide (IBDG), both of which yield blue or purple deposits, have been found very useful.[77,78,200] For example, on BCIG-containing "ColiChrome 2" plates (RCR Scientific, Inc, Goshen, Indiana), coliforms grow as red colonies; *E. coli* as blue or purple.

The glucuronidase-based methods provide identification and enumeration systems comparing favorably with conventional *E. coli* methods, and reduce assay times to 24 hours or less. It should be noted that while 95% to 97% of *E. coli* strains are glucuronidase-positive, about 50% of *Shigella* and 30% of *Salmonella* strains show glucuronidase activity and also grow at 44.5° C, a common incubation temperature for *E. coli*.[48,71,120,179] Thus, without confirmation, tests may better be described as assays of hygienic quality rather than of *E. coli*. Interference by intrinsic glucuronidase activity has been reported from oysters[123] and some freshwater and marine plants.[49] In contrast, many pathogenic strains of *E. coli* (eg, *E. coli* O157:H7) are glucuronidase-negative.[249]

Galactoside substrates are typified by o-nitrophenyl-ß-D-galactopyranoside (ONPG), which is lysed by galactosidase-positive coliforms to yield yellow o-nitrophenol during incubation at 35° C for 24 hours. ONPG is frequently combined with MUG in kits to permit detecting both total coliforms and *E. coli* in one test; tubes turning yellow (coliform-positive) during incubation are further examined for fluoresence under UV light. Kits such as Colilert (IDEXX Laboratories Inc, Portland, Maine) and Coliquik (Hach Co., Loveland, Colorado) were developed for detecting total coliforms and *E. coli* in waters, for which application they perform satisfactorily.[33,174] They may be usable with foods, provided the sample does not contain interfering enzyme activity; in the Colilert system, ingenious "MPN plate" (Simplate) accessories permit instantaneous distribution of a sample-substrate mixture into 84 or 198 wells for MPN enumeration. Other galactosidase substrates include 5-bromo-4-chloro-3-indolyl-ß-D-galactopyranoside or X-gal[143,144] and 4-methylumbelliferone-β-D-galactoside or MUGA.[29] In Rambach agar,[198] improved diagnostic capability is achieved by capitalizing on the ability of salmonellae to produce acid from propylene glycol. The medium contains propylene glycol, X-Gal, and neutral red; *Salmonella* colonies are bright red (neutral red precipitated by acid) while coliforms are blue (galactosidase activity) or violet (galactosidase activity plus acid formation). See Chapter 62 for further information on the use of chromogenic substrates for microbial detection.

Turbidity. The growth of microorganisms in a clear broth medium increases its turbidity and absorbance, a change that can be measured by spectrophotometer or nephelometer when cell densities exceed 10^6 ml^{-1}. Under well-defined conditions, the time required for the broth to achieve a certain absorbance is a reasonably consistent function of the inoculum, allowing estimation of the initial concentration of microbes. Homogenized foods are not ideal subjects for turbidimetry because their intrinsic turbidity signal may change with time (settling, enzymic activity); however, one can use turbidimetry for food suspensions if the inocula used are dilute enough to avoid excessive background noise.

A commercial turbidimeter (Bioscreen Analysis System, Labsystem, Helsinki, Finland) measures bacterial growth in a vertical optical pathway. Turbidity is read every 10 minutes at 620 nm. The system also contains a dispenser dilution unit and an incubator/shaker. Samples are incubated in microtiter plate-type vessels. The instrument stores the turbidity data and, after incubation, the individual growth curves of each well can be further analyzed. The system has been used to predict the number of cfu (total count) in a variety of food products including raw milk sausage, hamburger, and french fries and minced meat. Small sample volume may be a restrictive factor, and because of the need to dilute the sample 1:10 or 1:100, detection times were longer than by impedimetry; however, both capital costs and costs of disposable items were lower than for their impedance counterparts.[116,150–152]

To derive useful mathematical models of microbial growth (predictive models), a forbidding number of combinations of growth conditions may need to be studied before good models can be formulated. Turbidimetry has found considerable application in the derivation of data for predictive models on account of its simplicity, ease of set up, and the low cost per test. However, caution must be applied in calibrating systems in terms of cfu/ml because the turbidimetric signal depends on the phase of growth of cells, and may, in any case, only yield a ($\log_{10}$) linear response over a very limited range of cell concentrations.[96,156]

Turbidimetry or absorbance is also used in commercial identification systems; for example, VIDAS (Vitek Immunodiagnostic System, bioMérieux, France). For this instrument, identification cards and strips are available for most species of food-interest, such as Gram-negative non-Enterobacteriaceae, Enterobacteriaceae, staphylococci and micrococci, corynebacteria, *Salmonella, Yersinia enterocolitica,* and *Shigella* spp. Identification cards are inoculated from purified culture suspensions, placed in the instrument's incubator and absorbance is read automatically at regular intervals. For salmonellae, results are usually available in 4 to 6 hours, with good confirmation rates.[122] The method has AOAC official action status for foodborne *Salmonella* and for screening of non-*Salmonella* isolates. The instrument can be obtained as part of a complete system which also includes an impedance instrument (MicroTeam).

61.3.8 Gas Liquid Chromatography

It is outside the scope of this chapter to discuss the power and utility of gas liquid chromatography

(GLC) in identifying microbial species after their isolation and purification. Microbial identification by GLC depends on the fact that, if organisms are grown under strictly controlled conditions, cellular fatty acid composition in the 9 to 20 carbon atom range is a stable and highly conserved genetic trait[58] resulting in GLC profiles from which cultures such as *Vibrio vulnificus* and *Listeria* spp. may be identified.[268] Because the same fatty acids tend to occur in foods, direct detection or identification of microbes in foods is rarely possible; however, the sensitivity of GLC places it among the most interesting of chemical methods for estimation of microbial presence in foods.

Because the quantities of specific chemicals generated by individual microbial cells (particularly bacteria) are very small, relatively large populations of cells are required if they are to be detected by direct analytical methods. For this reason, despite its sensitivity, the use of GLC with foods is still confined to the estimation of spoilage flora. For example, the presence of D-lactate, acetate, and ethanol were correlated with deterioration of vacuum-packed or modified atmosphere-stored meats,[23,46,47,176] and the presence of D-alanine in fruit juices was a valuable indicator of microbial growth.[83]

Direct determination of volatiles in headspaces by GLC is particularly useful because no step is required to separate the analyte from food material. The technique was applied successfully to determination of total mesophilic bacteria or total coliforms in hamburgers. The method involved sequential analysis of carbon dioxide (CO_2) concentrations in equilibrium with headspaces of vials containing the inocula in suitable media. Linear relationships and excellent correlations between the time taken to reach a 5% level of CO_2 and the plate count ($r = 0.985$ and 0.966, for total count and coliforms, respectively) existed over a range of 10^2 to 10^8 cfu g^{-1}. Minimum detection times ranged from 5 to 17 hours and 4 to 14 hours, respectively, and the GLC measurement time itself was 3.5 minutes.[9] In routine use, only five to six injections were necessary to measure the minimum detection time for any sample. In other studies, the formation of hydrogen sulphide over aerobically stored meats may result from growth of Enterobacteriaceae and indicates a hygiene problem, while lactic bacteria may produce H_2S in vacuum-packed red meats.[23,59]

In some situations, GLC cannot only determine the presence of spoilage microbes in food products, but even partially differentiate them. Production of n-butyric acid and D(–) 2,3-butanediol served to differentiate sporeformers from nonsporeformers in cases of swelling of low-acid canned foods,[210] and the presence of butyric acid indicated clostridial contamination in commercially sterile vegetables, fruits, meats, fish, and dairy products.[68] Detection of n-butyrate helped establish the presence of *Clostridium estertheticum* and *C. laramie* in incidents of spoilage of vacuum packed raw beef.[40,46,47,118]

61.4 CONCLUDING REMARKS

The status and future for analytical food microbiology seem much brighter than they did even 10 years ago. Increased public concern with the microbial quality of foods, and the need for manufacturers to provide evidence to their customers that quality indices have been met, has spurred development of an enormous industry of kits and instruments. Whereas just a few years ago, detection of many pathogenic species required 5 or even 10 days, an equivalent analysis can usually be executed in 2 days, sometimes even in 1 day.

However, the value of "very fast" analyses to provide assurance of microbiological quality and safety is increasingly questioned. In a world of international food trade where safety is increasingly sought under the HACCP approach, it is unlikely that processes will ever be controlled by using tests for microorganisms; an exception would be foods where no other means of control is available, methods used for control are unknown, or foods are destined for sensitive consumers. Even if tests sufficiently rapid to permit corrective action to be taken online existed, the statistics of sampling plans practically means that the microbiologist's chances of reliably detecting defective (out of control) lots is very low.[104] (See also Chapter 60.) In HACCP-based industries, control over physical and chemical aspects of the microbial environment, for example, through using surface ATP measurement to indicate improper cleaning, or residual enzyme activity to indicate inadequate cooking, is likely to remain a better approach than attempting to detect the microbes themselves.

In the next few years, increasing use of technologies such as irradiation, flash-photolysis, and pressurization for controlling microbial pathogens in foods, may reduce even further the value of microbiological testing of foods as such. The future of microbiological testing probably lies in such areas as

Next Page

monitoring at the farm level (eg, to ensure control over the production of the animal and plant raw materials); in verifying control over environments of processing plants, distribution, and catering systems; and in providing compliance with regulatory requirements imposed on the industry, such as the mandated testing of carcasses for levels of *E. coli* and presence of *Salmonella* under the "Mega Reg" of the US Department of Agriculture.[261] Other major areas of application of microbiological testing will likely be in trouble-shooting problems occurring in the food industry and (despite the promise of HACCP) investigation of outbreaks of foodborne disease.

For some, but probably a few of these applications, tests should be as rapid as possible. Thus when sampling plant environments, it may be possible to collect the target organism with minimal interfering background material, which can be a great advantage to rapid analysis. At other times, however, the analyte will be in the presence of food, feces, or other problematic material, and the potential for very rapid tests can be expected to rely heavily on the availability of suitable techniques to separate and purify the analyte before analysis. In this respect, there is an urgent need to develop far more sensitive and reliable methods for detecting pathogenic viruses; these methods will almost certainly be based on nucleic acid amplifications methods. The current susceptibility of these techniques to interference by foods, and sanitizers emphasizes the need for more research into methods of separation and purification of these and other pathogenic agents.

In many other situations, extreme rapidity is not required. The centralized corporate control needed by organizations operating under ISO or total quality management (TQM) may be better served by methods capable of feeding data into information management systems. At the same time, however, there is a great potential for microbiological sampling and testing methods or devices with features such as low cost and high reliability, and being able to deliver reliable data when used by relatively unskilled personnel, perhaps even ensuring that the operator cannot sample the wrong location or miss an important spot. The tendency has been to direct the development of microbiological methods and testing equipment toward meeting the needs and wants of developed countries, as this is where the most profitable developments can be marketed. However, globalization of the world trade in foodstuffs and World Trade Organization agreements has led to the need to accommodate products from Third World countries where the degree of control expected in developed countries cannot be so easily be achieved at present because of the availability of resources and difficulty in controlling the food chain. This suggests the possibility of a huge potential market for devices more specifically developed for these regions.

62.1 INTRODUCTION

Traditional methods for the detection, enumeration, and identification of microorganisms in foods depend to a large extent on using suitable culture media. To detect specific microorganisms, which very often only form a very small proportion of the total microorganisms present, selective media are used that enhance the growth of the target microorganism(s) (eg, pathogens) and suppress the growth of the rest. Diagnostic characteristics may be incorporated into such media, allowing recognition of the target microorganism(s) by a characteristic reaction such as a color change. Some foods exposed to freezing or mild heat treatments or preserved with chemical agents or by low water activity or low pH may contain microorganisms that are sublethally injured, and resuscitation conditions are then required before these bacteria can be reliably detected by growth in, or on, selective media. Other foods may develop a flora reflecting the preservation conditions and may require special media and practices for the detection of certain microorganisms,[61] for example, halophiles in highly salted fish products and osmophiles in foods preserved using sugar.

When testing food samples for the presence of general or specific groups of microorganisms, it is essential that only media and methods be used that have proven reliability and reproducibility in different laboratories, so that decisions made on the results of the analysis are assured.[49] Thus quality assurance (QA), the continued monitoring of working practices, equipment, and reagents, including the quality assessment of media, is essential, and extensive interlaboratory trials should be undertaken to demonstrate the value of both media and methods before they are adopted as standard practice or by official standards organizations. This chapter will highlight the essential general features of cultural methods and their use in the laboratory.

62.2 BACKGROUND

Many of the selective enrichment broths and differential agars used for detecting and isolating foodborne pathogens are based on clinical methods, adapted by food microbiologists to give the greater sensitivity and selectivity required for the microbiological analysis of foods. Microorganisms residing on humans and animals, be they pathogens,[69,122] commensals, or otherwise, generally are transient in the wider environment, and often exist outside their normal habitats in an attenuated or stressed physiological state.[143] In foodstuffs, such microorganisms may be further stressed by the use of preservation methods that are inhibitory to microbial growth, such as freezing or drying, but that may allow the survival of microorganisms in an attenuated form for long periods.[60]

To make a reliable and accurate analysis, the microbiologist must remove a representative sample from a food and transfer this sample to the laboratory so that the target microorganism(s) remains unchanged in numbers and characteristics. How well this task is performed reflects the statistical reliability of the sampling procedure (Chapter 60) and good laboratory practice that allows sufficient attention to the essential conditions required at all stages of analysis. These include media selection, formulation and preparation, sample storage and preparation for analysis, incubation conditions for resuscitation and growth, and appropriate isolation and recognition methods.

The range of methods used in food microbiology includes qualitative presence/absence tests, often used for pathogen detection, and quantitative methods used for the enumeration of viable cells of all types of microorganisms, and the appropriate use of nonselective broths or agars, recovery and/or selective enrichment broth, and/or differential or diagnostic agars. Tests may use a single medium or a sequence of liquid and solid media singly or in parallel.[171] Many of the analytical methods and media formulations that have become widely used in the microbiological examination of foods have been compiled into textbooks or manuals (eg, *Bacteriological Analytical Manual*;[50] *Compendium of Methods for the Microbiological Examination of Foods*;[2] *Foodborne Pathogens—An Illustrated Text*;[168] *Foodborne Microorganisms of Public Health Significance*;[7] *Microorganisms in Foods—Their Significance and Methods of Enumeration*;[79] *Practical Food Microbiology*;[141] and *Culture Media for Food Microbiology*.[30]) An extensive compilation of media for wider use has been published in the *CRC Handbook of Microbiological Media*.[6] Several hundreds of these formulations have been produced by commercial manufacturers as either dehydrated media or as ready-to-use media and are described in their company manuals.

62.3 PRINCIPLES OF MEDIA FORMULATION

The formulation of a new culture medium is greatly assisted by identifying, at the time of development, those attributes needed to improve performance over existing media used for the same purpose. This need may be the outcome of various observations, the suspicion that some strains or injured cells of the targeted species are not detected by existing liquid or solid media, that overgrowth by competitive flora masks the target organism, or that a better means to identify or speed organism recognition would be beneficial. From this it is possible to devise a strategy to achieve these goals. This could comprise consideration and determination of the following:

1. Scope of application and likely format of method
2. Identification of appropriate strains of target and competitor organisms
3. Determination of nutritional and other requirements for the optimal growth of undamaged cells and the recovery of likely damaged cells of the target microorganism
4. Determination of the optimum concentration, effective range, and the compatibility of likely selective and diagnostic agents to be incorporated in the medium
5. Establishment of optimum incubation conditions including temperature, time, and atmosphere
6. Assessment of performance against an established method(s) using a range of isolates from appropriate sources and using naturally contaminated foodstuffs
7. Validation of method by interlaboratory trials using comparative testing with a range of inoculated and naturally contaminated food and environmental samples.

62.4 CULTURE MEDIA COMPONENTS

Culture media are composed of a wide range of organic and inorganic components—some, such as the inorganic components, are chemically well-defined and of high purity and constant reproducibility, other components (mainly organic) are ill-defined, incompletely characterized, and with a variability that is poorly described or unknown.[22] Sources of nitrogen for growth may be ammonium ions, amino acids, peptones, or peptides; carbon as an energy source is most readily obtained from mono- and disaccharides; various inorganic salts, particularly phosphates, are added for buffering purposes and to aid metabolism together with Ca^{++}, Fe^{+++}, Mg^{++}, and Mn^{++}; and other trace metals commonly are present as impurities in the complex organic components. Some microorganisms need, or their growth is stimulated by, various vitamins, co-enzymes, and substances that reduce the toxic effect of oxygen radicals.[23,55] Some of these may be derived by the addition of whole blood, globin, serum, hemin, or egg yolk, compounds that are difficult to analyze but, being of direct biological origin, are of a more constant composition than the manufactured peptones and meat and yeast extracts. Extensive chemical analysis of complex organic components[128] prior to incorporation into media may fail to measure the critical components that allow optimum growth of specific microorganisms or production of toxins,[163] and growth studies with selected test strains may be the most effective means of identifying suitable batches of components. Many supplements to media are added at the time of use because they are unstable, have a short shelf life in solution, or are incompatible with the basic formulation. These components include antibiotics, egg-yolk emulsion, and blood components.

62.5 CHEMICALLY DEFINED MEDIA

Chemically defined media contain only constituents of known molecular structure and purity. They may be formulated as a special elective growth medium "which by restriction of nutrients and design of other components will allow the selective growth of the targeted organism(s) only,"[22] as the basis of a biochemical identification test or as a research tool in genetic or metabolic pathway studies. However, growth rate and microbial yield usually are lower than in complex media,[109] and few chemically defined media have gained wide application in food microbiology. An exception is minerals modified glutamate medium (MMGM), used for the detection of coliforms and *Escherichia coli*. It was introduced at a time when MacConkey broth was inconsistent in performance due to the variability of commercially available bile salts and peptone.[131] The medium has undergone extensive refinement and validation over 25 years, first used for the examination of drinking water[134] and later used as a resuscitation medium for the detection of *E. coli* in foods;[73,74] MMGM also allows the detection of stressed coliforms and *E. coli* surviving marginal chlorination in water.[133] The various modifications to MMGM are shown in Table 62–1 as an illustration of how a method may evolve over time.

62.6 NUTRITIONALLY COMPLEX MEDIA

Nutritionally complex media contain natural growth materials, the chemical composition of which is not completely defined.

62.6.1 Nutrient Components

Amino/Nitrogen Nutrients. Peptones and protein hydrolysates are the prime source of amino nitrogen in all complex culture media. They are produced by media manufacturers and specialist companies by industrial processes considerably modified from the original methods used in the early bacteriological media kitchens.[22] They are stabilized by concentration to pastes or powders and packaged to give a long shelf life. Manufacturers provide a range of peptones according to either the raw material used, the method of preparation, or by the blending of these.[159] They are sold under a range of product names.[23] Peptones may be broadly divided into the following groups.

- Peptones from animal tissues. Lean meat: peptic, tryptic, and pancreatic digests. Liver: papaic digest. Gelatin: pancreatic digest.
- Peptones from milk. Casein: hydrolysates prepared enzymatically by peptic, tryptic, or pancreatic enzymes or by acid treatment. Lactalbumin: pancreatic hydrolysates.
- Peptones from vegetable tissues. Soya meal: papaic digest, and products from groundnut and sunflower seed. All of these are rich in various natural carbohydrates unless removed by further processing.

All of these products differ in their peptide, peptone, and amino acid composition depending on their origin and the manufacturing process (Tables 62–2 and 62–3). Some products are formulated from mixed peptones to give a particular growth characteristic (eg, special peptone, proteose peptone, tryptose). Despite control exercised by the manufacturer, batch-to-batch variation can still affect optimal growth or maximal production of toxins.[163] The range of variation of the constituents of peptones is indicated in Tables 62–2 and 62–3.[22]

PHLS, UK Public Health Laboratory Service

For the growth of some fastidious pathogens, certain peptones are beneficial or essential. For instance, an iron-rich liver digest peptone is incorporated into a *Campylobacter*-selective medium to enhance the growth and aerotolerance of fastidious *Campylobacter* species.[20,149] Tryptone is a rich source of tryptophan and is a component of media used to test the ability of bacteria to produce indole from tryptophan. Soya peptone is used in modified Rappaport-Vassiliadis broth where it enhances the growth of salmonella and maintains the pH of the prepared medium during storage.[165]

Extracts. Aqueous extracts of animal, plant, or yeast cells contain less organic nitrogen than the acid or enzyme extraction methods and, therefore, sustain less microbial growth when used alone. However, importantly, they contain many growth factors destroyed by the manufacturing process used for the production of peptones. Extracts are therefore often used to complement the peptones and hydrolysates in media formulations.

Meat extract originally was produced in the laboratory media kitchen by the cold infusion of lean, fat-free meat such as beef heart,[176] then commercially as a paste by concentration of the extract to >20% solids and now as a more refined, sugar-free, dried powder. The composition of the meat extract depends on the meat source time and temperature of extraction.[13] Meat extracts contain amino acids, peptides, purines, organic acids, urea, ammonium salts, and coloring matter and are highly buffered: they are also rich in B vitamins but low in thiamine.[13,159,176]

Yeast extract is a widely used nutrient component in culture media, being composed of amino acids, peptides, water soluble vitamins (including thiamine), nucleic acid residues, and the carbohydrates glycogen, trehalose, and glucose (Tables 62–2 and 62–3). Bacteriological yeast extract is prepared by the lysis of washed cells of *Saccharomyces* species using a mechanical means and slowly raising the temperature to 50° C; isopropyl alcohol may be added to improve lysis. The cell-free extract is then pasteurized to destroy the enzymes present and rapidly concentrated either to a paste or a spray-dried powder; Bridson and Brecker demonstrated that yeast extract derived from Bakers' yeast gave superior growth characteristics to that from Brewers' yeast, reflecting the original growth media used in the production of these yeasts.[23]

Malt extract, the water-soluble wort of malted barley, is used for the growth of yeast and molds. Its final composition will vary according to the species of barley used, its condition at harvest, and the conditions at the time of fermentation. Malt extract has a pH of about 5.5 and is rich in sugars and amino-compounds (Tables 62–2 and 62–3). A comparison of the vitamin content of meat, malt, and yeast extracts is given in Table 62–4.

62.6.2 Carbohydrates

Many media formulations contain added glucose at concentrations of 1% or less to supply a readily usable energy source. Other media contain a specific carbohydrate that, through its use, acts as an indicator for a particular group of organisms, such as lac-

tose in the presence of bile by coliform organisms in MacConkey broth or on violet red bile agar. Some media contain a mixture of carbohydrates such as lactose and sucrose in phenol red brilliant green agar to encompass either greater differentiation between targeted and nontargeted organisms or to increase the range of bacteria targeted. The ability of microorganisms to use a carbohydrate may also be used as a means of identification (eg, mannitol by *Staphylococcus aureus* in Vogel-Johnson agar). An array of individual carbohydrates, each in a nutritionally simple base medium or agar together with a pH indicator (eg, purple agar base), is used as part of a battery of biochemical tests to differentiate one species from another.[11] To aid in the repair of some bacteria and stimulate growth of others, pyruvate replaces a carbohydrate source, as in Baird-Parker agar,[8,75] and some media such as Cefsulodin Irgasan Novobiocin agar[126] or pyruvate egg yolk mannitol bromothymol blue agar (PEMBA)[72] contain both pyruvate for repair and mannitol for differentiation. Pyruvate may act as a carbon source or as a means to neutralize superoxide radicals and thereby reduce the toxicity of media, particularly to injured cells with damaged membranes.[25,55] In many media, no carbohydrates are added and the small amounts of carbohydrates present in other components are readily used by the organism to provide energy. For example, the growth of a *S. aureus* in heart infusion broth first uses carbohydrates present from its meat infusion, causing a fall in pH, and when these carbohydrates are exhausted the pH increases as a result of decarboxylation of amino acids. Where carbohydrates present in media are not used as an indicator of metabolism, then some degree of buffering to maintain the pH at the optimum for growth or selective action is necessary.

62.6.3 Buffers and pH Indicators

Some buffering results from the presence of peptones and amino acids, but when carbohydrates are included in a medium, this buffering capacity is insufficient to maintain an optimal pH. An effective buffering system is one that has maximum buffering capacity at the desired pH. This maximum is around the pK_a of either the weak acid or base component of the buffer. Thus for neutral media at pH between 6.8 and 7.2, hydrogen phosphate and dihydrogen phosphate ($pK_a = 7.21$) as either sodium or potassium salts are commonly used. In an acidic medium such as lactobacillus sorbic acid agar, with a pH of 5.0, a citrate/acetate buffer is used. An alternative means of maintaining neutrality (eg, in tetrathionate broth) is to use chalk to neutralize the weak acids formed from bacterial metabolism. Indicators of pH change are selected so that their color change corresponds to the change in pH of the medium. Those in common use in bacteriological media are neutral red with change in color from red to amber through pH 6.9 to 8.0; phenol red with change in color from yellow to red through pH 6.8 to 8.4; bromothymol blue changing from yellow to blue through pH 6.9 to 8.0; bromocresol purple changing from yellow to violet through pH 5.3 to 6.8.

Phosphates in combination with glucose in media can cause the accumulation of hydrogen peroxide in autoclaved media exposed to oxygen, resulting in possible increased toxicity to injured microorganisms.[23]

62.7 SELECTIVE AGENTS

A wide range of chemical substances is used to generate the selective conditions that will favor the growth of one species or a related group of microorganisms and/or suppress the growth of other microorganisms present in a culture medium. These selective agents include antibiotics, dyes, surface-active agents, and inorganic and organic chemicals variously having a wide or more specific inhibitory action. Each agent may be used alone or in combination. The selective action may be achieved by one or several of the following means:

Inhibition of Competitors. Bactericidal action may cause immediate or progressive decline in numbers. Bacteriostatic action may ensure little or no increase in the original numbers of competitors and a probable slow decline in their viability.

Differences in Lag Time. Some targeted microorganism(s) have a shorter lag time in the selective conditions and thus outgrow other organisms.

Change in Relative Growth Rate. If the targeted microorganism has a shorter generation time than its competitors in the selective conditions, an increase in its relative numbers results.

Incubation Conditions. Use of an appropriate incubation temperature can enhance the growth of a targeted microorganism, such as growth at 55° C for the selection of thermophiles. Use of an optimum incubation atmosphere can enable selection of the targeted microorganism (ie, aerobes, strict or less-sensitive anaerobes, microaerophilic species).

Use of the ideal selective conditions would achieve the inhibition of the most robust competitors while allowing good growth of the most sensitive targeted microorganism; however, the probability of a formulation achieving this balance is, at best, very rare. Thus in liquid selective media, the targeted microorganisms may dominate all other species present or may only form a small proportion of the total flora. On solid selective media, the targeted microorganism should grow well, while competitors grow less well, are partially inhibited and give rise to microcolonies, remain viable but fail to divide, or are killed. Where microcolonies are formed or cells remain viable, these may inadvertently be picked from the medium together with the targeted colony when subculturing. Here, direct streaking onto a nonselective agar medium rather than inoculation into a liquid medium is necessary to recognize whether the subculture is mixed and to allow the isolation of a pure culture. Many selective agents, while not inhibitory to the growth of robust strains of the targeted organism, are inhibitory to these same strains if stressed or damaged. Mossell and van Netton have reviewed the harmful effects of selective agents in culture media that are inhibitory to the recovery of injured foodborne microorganisms.[115]

Antibiotics. These are the most widely used selective agents because of the numbers available, and the differing spectra of their antimicrobial activity. Examples of those used in food microbiology are listed in Table 62–5.

Where antibiotic solutions are prepared in the laboratory from dry powders, it is essential that the antimicrobial activity of the antibiotic is known, and that the amount weighed out is adjusted accordingly so that the intended concentration is used.

Dyes. Prior to the advent of antibiotics, dyes were studied extensively for their antimicrobial properties and their use in clinical medicine and in the laboratory. The triphenylmethane dyes were the most effective in culture media and are still used in food microbiology to inhibit Gram-positive bacteria.[52] Some dyes show some differential activity within the Gram-positive species.[54] The acridine dyes, of which acriflavine (a variable mixture of 3,6-diaminoacridine dihydrochloride and 3,6-diamino-10-methylacridinium chloride) are the most commonly used, are very inhibitory to injured bacteria and mutagenic to others.[1] Brilliant green is inactivated by heat, bile salts, and light; therefore, appropriate conditions in the preparation, storage, and use of media should be implemented.[9,67,164] As the chemical composition, purity, and therefore antibacterial activity of dyes can be variable, checks with appropriately sensitive test strains are essential in quality assessment of media.[121]

Surface-Active Agents. Three bile products are widely used in selective media. These are: ox bile, a crude dried preparation of variable composition; bile salts, a partially purified material obtained by acid precipitation that separates the bile salts from the bile pigments and other components in the crude bile; and bile salts No. 3, the most refined material, containing specially modified fractions of the bile acids. Compared with ox bile, the bile from other animals will show differences in selectivity. Other refined products from crude bile such as desoxycholate and taurocholate also are used as inhibitors of Gram-positive bacteria in enteric media. Because of the biological variation in crude bile and also differences in activity of the manufactured bile products, sodium lauryl sulphate may be used as an

alternative surface-active agent to suppress the growth of Gram-positive bacteria; it also has the advantage of a defined chemical composition that gives a more consistent antimicrobial activity.

Inorganic Chemicals. These include tetrathionate and selenite, used as selective agents in media for salmonellas; potassium tellurite and lithium chloride used to inhibit Gram-negative species in Baird-Parker agar and other media; dichloran (2,6 dichloro-4-nitroanaline) used in mycological media to inhibit bacteria and slow the spreading of colonies of fungi; irgasan, a disinfectant, used as a selective agent in media for the isolation of *Yersinia* species; thallous acetate used as a the selective agent in thallous acetate tetrazolium glucose agar for the differentiation of *Enterococcus faecalis* from *Enterococcus faecium*; and cetrimide (cetylmethyl ammonium bromide) in cephaloridine fucidin cetrimide agar for isolating *Pseudomonas* species.

62.8 DILUENTS

For the preparation of suspensions and dilutions of foodstuffs, 0.1% peptone water is most commonly used. However, when requiring a neutral suspension, the resulting mixture may require pH adjustment when used to prepare suspensions of acidic foods. The use of buffered peptone water for such products often can avoid this pH adjustment; the risk of extraneous contamination during pH adjustment is also prevented. Peptone, in the absence of significant amounts of other organic matter, also neutralizes the effect of any low levels of inhibitory metals that may originate from external sources, such as water or glass containers.[92] In a study of the survival of *Staphylococcus aureus*, *Streptococcus pyogenes*, *Escherichia coli*, and *Salmonella typhimurium* in six diluents during their storage for 2 hours at room temperature, five of the diluents were bactericidal to one or more test strains, the sixth diluent, 0.1% peptone water, caused little change in any of the viable counts.[95] In a further study of the effect of seven diluents on the viability of yeasts isolated from foods, 0.1% yeast extract and 0.1% malt extract allowed the greatest survival and distilled water and 0.85% saline the least.[104] The salt-tolerant yeast *Debaryomyces hansenii*[3] and xerophilic yeasts (eg, *Zygosaccharomyces* species, *Schizosaccharomyces pombe)* required osmotic protection (eg, use of 20% to 30% glycerol in peptone water) when serially diluted prior to plating.[16] While fungal spores appear unaffected by diluents and 0.1% peptone water generally is regarded as satisfactory, the optimum conditions for handling fungal hyphae are not well described.[130]

For presence/absence tests for specific microorganisms in foods, it is common practice to dilute samples directly into the growth medium and to homogenize the mixture. Certain foods need specific treatments to make a well-dispersed suspension. For example, chocolate requires warming at 45° C until melted, and samples rich in fat require the addition of small quantities of sterile Triton X-100 or Tween 80. When preparing dried materials for the examination of Gram-negative pathogens by presence/absence tests, controlled rehydration to minimize osmotic shock to damaged cells is beneficial to their recovery and detection. Two methods to achieve this have been described: by carefully layering the dried sample onto the surface of the liquid so that the sample slowly absorbs water for up to 30 minutes before homogenization or the stepwise addition of diluent, starting with a 1 to 1 w/v ratio and progressing to a final 1:10 ratio through about 30 minutes.[167]

To neutralize any antimicrobial agents that may be present on food processing equipment after sanitation, swabs used to check the effectiveness of sanitation should be placed in universal quenching agent (0.1% peptone, 0.1% sodium thiosulphate, 0.5% Tween 80, and 0.7% lecithin) prior to plating onto microbiological media.

62.9 MICROBIAL GROWTH MEDIA

As well as classification by composition, growth media may also be characterized according to use; such classification will be used in this section of the chapter.

62.9.1 Liquid Media

General Purpose Nonselective Broths. These comprise broths having no selective or differential features, such as nutrient broth or heart infusion broth. These are used for general tasks such as the growth of microorganisms to obtain pure cultures or to produce inocula for further testing, such as species identification or strain characterization. Nonselective broths also have been formulated for the growth of specific groups of organisms that benefit from the presence of particular growth substrates, for example all-purpose Tween broth for the growth of lactic acid bacteria,[138] TSB (tryptone soy broth) for the growth of yeasts, and Robertson's cooked meat broth[142] for the growth of microaerophilic or anaerobic microorganisms. These media can be used for the short-term maintenance of a culture for periods of about 1 week for many, but not all, bacteria. While technically simple, repeated subculture in broth has a risk of contamination and an undetected change in strain characteristics. For the characterization of an organism, it is preferable to grow the inoculum in a complex medium rather than a defined medium because the former will lead to the better expression of the biochemical and morphological characteristics of the organism.[28]

Pre-enrichment Broths. Pre-enrichment media are nonselective media formulated to allow the repair of any sublethally injured microorganisms present prior to their exposure to the selective agents in selective enrichment broths.[44] Direct inoculation of injured cells into selective media can result in the death of some or all of them, the latter giving a false-negative result. Some selective broths are formulated to overcome injury, as is Giolitti-Cantoni broth for the detection of low numbers of *Staphylococcus aureus* in foods.[57] Suitable pre-enrichment conditions, in combination with productive selective enrichments, are essential for the reliable detection of low numbers of foodborne pathogens in foodstuffs. Much of the investigative work done on the advantages of various formulations of pre-enrichment broths (Table 62–6) concerns their use for detecting low numbers of salmonella in raw materials for processed foods or final products.

While the principles involved are described here in relation to salmonella, they also apply to other injured, pathogenic bacteria. During the incubation of a pre-enrichment culture of a food sample, injured and uninjured cells of salmonellas must recover, and then multiply to numbers that ensure both their transfer on subculture to a selective medium and their survival in the selective medium in sufficient numbers that their growth is ensured. At the end of pre-enrichment incubation, cells must not be in any way attenuated or they may be sensitive to the selective agents in the selective medium. A nonselective pre-enrichment culture will allow the growth of the majority of the microorganisms present in a food sample; these microorganisms may overgrow the target microorganism. By the time repair has occurred, other uninjured or less-injured microorganisms may form the dominant species. When the dominant species enter their own stationary phase, they may inhibit the further growth of all other species present, including the targeted species that may still be in such small numbers that their detection after the selective enrichment stage is uncertain (see the pre-enrichment stage in Figure 62–1). This stationary phase inhibition effect was first described by Jameson[89] and is discussed in detail later.

The use of short pre-enrichment incubation (eg, 6 to 8 hours), while permitting same-day subculture, is not sufficient to allow the recovery and multipli-

Table 62–6 Development and Use of Pre-enrichment Broths for the Isolation of *Salmonella* Species in Foods and Animal Feeds

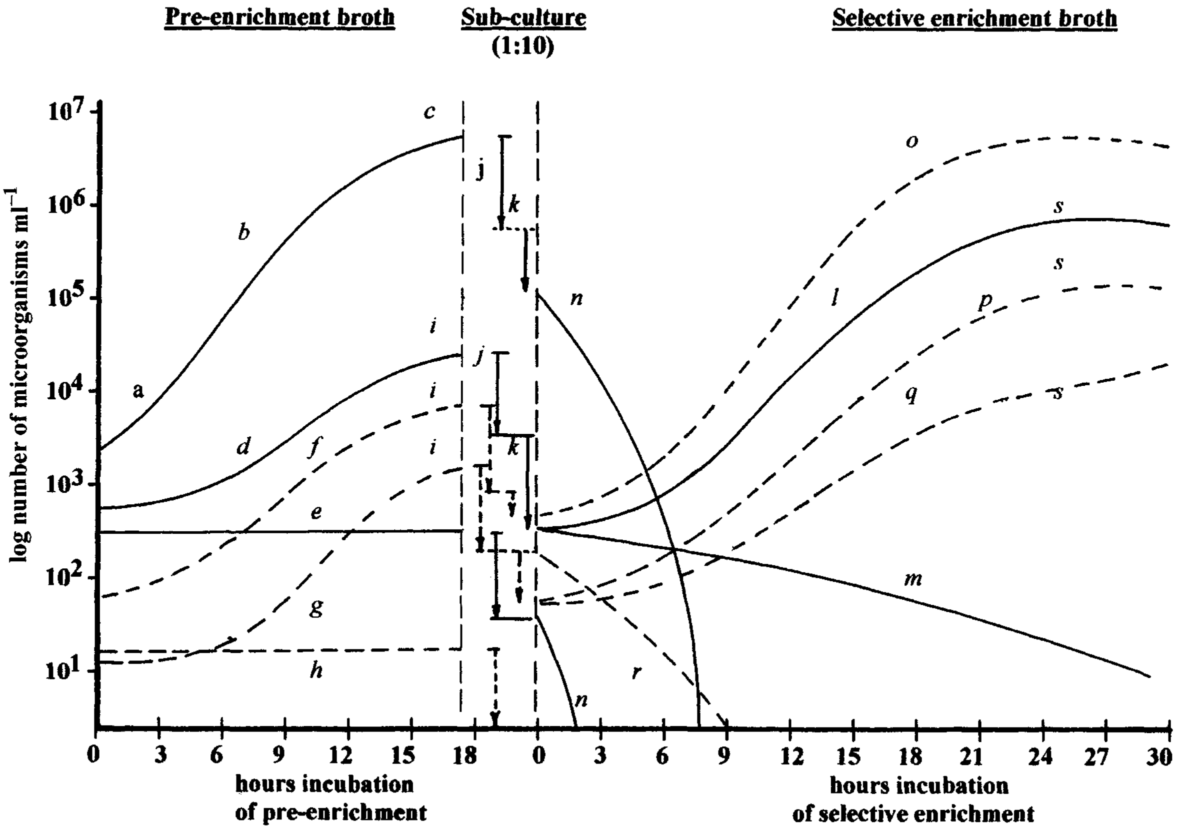
Date	*Medium*	*Purpose*	*Comments*	*Reference*
1955	Nutrient broth	Recovery of *S. paratyphi* from flour	>10-fold increase in MPN estimates	Thompson[161]
1961	Lactose broth	Dried foods and egg products	Improved detection rate	North[120]
1963	Nutrient broth	Egg and egg products	Improved detection rates	Hobbs & Alison[70]
1972	Buffered peptone water	All dry foods, processed foods, animal feeds, meats	Resuscitation of stressed cells	van Schothorst & van Leusden[166]
1974	Buffered peptone water	Minced meat and animal feed	Resuscitation of stressed cells	Edel & Kampelmacher[44] and ISO 6579[86]
1977	Lactose broth and peptone water	Frozen sweet corn	Study on maintenance of pH during incubation	Sadovski[144]
1977	Lactose broth	Recommended for general use (eg, milk and milk products, dry powdered food mixes, meats, fish, dried vegetables and fruits)	Fall in pH to 5.5–5.0 from lactose use selects for salmonella. Below pH 5.0 becomes inhibitory.	BAM 1997[50]
1978	Eugen broth, Clausen broth, Tergitol broth, EE broth, GN broth	Wide range of foods of low- and high-moisture content; animal feeding stuffs	Study to shorten incubation times	D'Aoust & Maishment[36]
1992	Distilled water + brilliant green	Dry whole milk, nonfat dry milk	Inhibition of Gram-positive flora in the reconstituted milk used as growth medium	BAM 1997[50]
1992	Trypticase soy broth	Whole eggs, spices, herbs	Neutralization of natural inhibitors in the test material	BAM 1997[50]
1992	Sterile nonfat dried milk	Candy and chocolate	Neutralization of natural inhibitors in the test material	BAM 1997[50]
1992	Trypticase soy broth + 0.5% K_2SO_4	Onion and garlic flake and powders at 1:10; allspice, cloves, cinnamon, and oregano at ≤ 1;100 dilution	Neutralization of natural inhibitors in the test material	BAM 1997[50]
1998	Buffered peptone water + enzymes	Digestion of gelling agents—starch, gums, and celluloses	Also in combination with 1:100 dilution	ISO 6579[86]

cation of all injured cells.[9,36,100,101] A general optimum time for conventional pre-enrichment incubation is 16 to 20 hours for salmonellas. This time is a compromise between a longer incubation time that may allow better recovery of severely damaged salmonellas, and the increased risk of decline in the physiological status of undamaged salmonellas and/or gross overgrowth by the competing bacteria in heavily contaminated samples. Where dilutions of a food material greater than 1 in 10 are necessary, to overcome, for example, naturally occurring inhibitory agents,[50] then a 20 hours to 24 hours incubation is recommended.

The use of chemically defined media may enable increased recovery of injured salmonellae, previously grown under minimum nutrient conditions, compared with those grown under rich nutrient conditions. This was demonstrated by the better recovery of heat-injured *Salmonella senftenberg* in chemically defined M9 medium than in nutrient broth and lactose broth with or without the addition of food samples.[175] The significance of this to the isolation of salmonella from foodstuffs is questionable because it is most likely that salmonella present in a food sample will be derived from a nutrient-rich environment, although the physiological status of the cell will be unknown depending on its past history. However, buffered peptone water, which is nutritionally less rich than nutrient or lactose broth, has been shown to be more effective for the repair of salmonella.[153]

Some injured salmonellae have prolonged repair times.[100] Using an automated growth analyzer, a device based on optical density measurement and able to study the growth from single-cell inocula in liquid media, Stephens et al.[153] demonstrated that the estimated lag (repair) times of heat-injured *S. typhimurium* cells varied from about 6 hours to >30 hours in buffered peptone water, TSB, lactose broth, and heart infusion broth. This effect was seen using different manufacturers' media and different batches of the same media from one manufacturer. As the number of injured cells added to each test unit increased above 1 cell, the apparent lag time decreased, being indicative of the growth of the least-damaged cells in each subpopulation. With a larger inoculum (ie, 10^2 to 10^3 cells) of injured cells, lag times similar to those determined by traditional methods from growth curves studies were obtained.[153] Evaluation of batches of peptone permitted the selection of the best product for the recovery of the injured cells. The variable lag time of individually injured salmonella cells subsequently was reduced by the addition of oxyrase® to the medium. This removed the toxic oxygen molecules in the medium and reduced the oxidative stress on the injured cells [Stephens, in press]. These findings have significant implications for the use of pre-enrichment and for our understanding of the performance of current methods to reliably recover one or a few (<5) injured salmonella in the most demanding test situations. Extended lag times also were found for attenuated *Listeria monocytogenes*[112] and *Escherichia coli* O157 [Stephens, in press]. Thus the individual cells of severely stressed Gram-positive or Gram-negative bacteria either require longer incubation times for repair than is currently practiced or re-formulation of the growth medium to give shorter recovery times.

Selective Enrichment Broths. Selective enrichment broths, with or without prior pre-enrichment, may be used as a single presence/absence test, or in a dilution series to estimate low numbers of targeted species using multiple tubes of media in a most probable number format.[119] In a liquid enrichment broth inoculated with a mixture of microorganisms, competitive growth occurs between all species able to tolerate and use the selective conditions. Rarely from a heterogeneously contaminated sample does any selective enrichment allow the growth of the targeted species alone.[93,125] Enrichment broths may be inoculated with either a food sample, a pre-enrichment broth, an environmental swab, a filtered water sample, or from a primary enrichment to give a further, secondary enrichment. In all these cases the targeted microorganisms generally comprise only a very small proportion of all the bacterial species present.[125] In some highly selective media, the inoculum of healthy cells of the targeted species may decline during adaptation to the new medium.[78,164,165] The selected microorganisms then grow to give a culture of unpredictable composition when the stationary phase is reached. It is therefore understandable that the performance of a formulation varies. Ideally the targeted microorganism will ultimately form the dominant bacterial species in the enrichment broth, but in most cases this is not so. Uninhibited competitors may also increase to high numbers either initially or as a result of the growth of the targeted species, changing the selective conditions of the medium. The effectiveness of each selective agent in a selective broth is influenced by any synergistic or antagonistic effects between the selective agents, especially antibiotics,[20,21] and by the components of the food sample diminishing their effectiveness.[148] Where alternative enrichment broths based on different selective agents are used in parallel, then where one medium fails to inhibit a dominant competitor another enrichment may be effective, so that



Events in pre-enrichment media during 18 hours incubation
a—lag period as measured by the total viable count
b—exponential phase of dominant microorganisms
c—initiation of stationary phase in the dominant species
d—growth curve of a nontarget species having a longer lag phase
e—nontarget species unable to grow but survives in the growth medium
f—targeted bacteria—growth curve from small numbers
g—targeted bacteria—growth curve of strain having a prolonged lag time
h—prolonged lag time of severely damaged target microorganism; doubtful detection
i—the Jameson effect—lesser populations passing into premature stationary phase as a result of (c)

Events occurring on subculture of pre-enrichment to selective enrichment broth
j—dilution of population (1/10, 1/00, or other)
k—variable degrees of death that occur with nontarget microorganisms on inoculation into the selective enrichment broth and possible decrease in numbers of some sensitive strains of the target organisms

Events during incubation of selective enrichment broth
The data assume that the targeted bacterium forms a minor part of the total population from the pre-enrichment broth
l—growth curve of a competitive species not inhibited by selective agents and part of the dominant flora of the pre-enrichment broth
m—decline of competitors unable to grow (bacteriostatic effect)
n—death of competitors (bactericidal effect)
o—growth curve of a robust target microorganism with shortest lag and generation time to form dominant species within 24 hours incubation
p—growth of a less vigorous target strain that forms a smaller proportion of the total population and may not be isolated when cultured onto selective agars at 24 hours
q—A poorly growing target strain that will not be isolated at 24 hours and numbers will increase during secondary phase enrichment
r—Target strain sensitive to a component of the selective enrichment (eg, brilliant green)
s—Jameson effect—the inhibition of other strains as the dominant strain enters its own stationary phase in the enrichment broth

Figure 62–1 Schematic Representation of the Range of Events That Can Occur during Pre-enrichment and Selective Enrichment Culture

Table 62–7 Isolation of Salmonella from 51 Samples of Liquid Whole Egg

	Salmonella Isolated after the Elapsed Incubation Times Stated						
Sample Number	*Pre-enrichment in Nutrient Broth and Subculture at 24 h and 48 h:*				*1st Tetrathionate broth*		*2nd Tetrathionate*
	24 h	*48 h*	*72 h*	*96 h*	*48 h*	*72 h*	*72 h*
1	-	-	-	-	-	-	++
2	-	-	-	-	+++	+++	+++
10	-	-	-	-	-	++	-
14	-	-	-	-	+	++	-
17	-	-	-	-	-	-	-
30	+	-	-	-	+++	+++	-
43	++	+	+	-	+++	+++	+++
44	-	-	-	-	+++	++	+++

There were 8 positive results obtained using pre-enrichment in nutrient broth and streaking, followed by selective enrichment for 24 hours and 48 hours in tetrathionate broth and further subculture at 24 hours into a further tetrathionate broth. All broths streaked onto bismuth sulphite agar.

the target species is subsequently detected.[37] Jameson[89] studied the interaction of proportions of different Enterobacteriaceae species in a salmonella-selective broth. Provided there were no antagonistic effects between the species, all were found to grow initially with very similar lag and generation times as when growing alone in that medium. When the culture approached the stationary phase, primarily due to the numbers of the dominant species, then cell division of all other species present simultaneously declined (Figure 62–1). This was irrespective of the stage at which the less numerous species were in their own growth cycle. Jameson described this as the primary stage of enrichment. It was subsequently followed, on extended incubation, by a secondary stage in which a succession of less numerous species grew to form a larger part of the total population. This secondary stage of multiplication was at rates considerably slower than those in the first stage. Even different strains of the same species (eg, *Escherichia coli* or *Salmonella*[68]) when grown together demonstrated this Jameson effect. Figure 62–1 depicts the various events that can occur in the use of pre-enrichment followed by selective enrichment.

Thus, cultures containing salmonella and plated onto selective agar media after 24, 48, 72, and 96 hours of incubation may be positive on one occasion but negative on another, or salmonellae may be isolated on all occasions (Table 62–7). This interactive effect was dependent on the initial numbers of salmonella and competitors present.[89] Park and Sanders also recommended that enrichment cultures used for the detection of *Campylobacter* species should continue for up to 96 hours to improve isolation rates.[123] Such culture dynamics probably contribute to the performance of cold enrichment previously used for the enrichment of *Yersinia* species[113,146] and *Listeria*.[99]

Some selective enrichment media now recommended for the detection of certain foodborne bacteria are very productive following continuous refinement of formulae over many years (eg, Rappaport-Vassiladis broth for *Salmonella*[169] and tryptose-sulphite-cycloserine agar for enumerating *Clostridium perfringens*[117]).

The selective action of some enrichment broths is not sufficiently good, however, to allow recovery of all targeted cells following pre-enrichment or the direct enrichment of heavily contaminated samples and, for these, other strategies have been developed. For example, in the detection of *Listeria* species a reduced level of selective agents in the primary selective medium is used in the International Standards Organization (ISO) and US Department of Agriculture Food Safety Inspection Service (USDA-FSIS) methods.[87,110] This allows recovery and growth of most listeria (severely injured cells may not recover), while having some selective action to minimize competition. A second enrichment broth is then inoculated to increase numbers to levels that are detectable when plated onto selective agars.

Another strategy is the combined use of two or three selective media based on different selective principles. Thus tetrathionate,[93] selenite,[97] or malachite green and pH[166] are widely used for salmonella isolation.[86] Where one medium fails to give detectable numbers of salmonella, another often succeeds.[67] Two enrichment broths are used in parallel in each of the ISO Standards for the detection of *Vibrio parahaemolyticus*,[82] *Yersinia enterocolitica*,[83] thermotolerant *Campylobacter* species,[85] and *L. monocytogenes*.[87]

A further enrichment culture strategy is the sequential addition of selective agents to permit resuscitation, then selection of target species. This principle was described for the isolation of *Campylobacter jejuni* and *C. coli*.[123,124] In the initial broth, pyruvate is used to aid recovery, and vancomycin and trimethoprim lactate are used to give some selectivity. After incubation at 32° C for 4 hours under microaerophilic conditions (by sparging with 5%O_2:10%CO_2:85%N_2), further antibiotics, cefoporazone, and cycloheximide are added and incubation is continued at 37° C for a further 2 hours before the temperature is raised to 42° C for 40 to 42 hours to increase selectivity prior to plating. Thus recovery of *Campylobacter* spp. and their exposure to the selective agents are progressive events. The US Food and Drug Administration's *Bacteriological Analytical Manual* method for isolating listeria adopted a similar technique with resuscitation in a pyruvate-containing medium before the addition of antibiotics.[50]

Secondary enrichment (not to be confused with secondary-phase enrichment described by Jameson[89]) may be used to advantage when primary selective enrichment fails to allow isolation of the target organism due to heavy overgrowth by competitors. Here the first enrichment is subcultured into a second enrichment broth and that is plated out after further incubation. Greater success may result when the second enrichment is based on different selective principles from the first enrichment. Thus improved performance and reliability result from a strategy that optimizes recovery of the most stressed, but viable, target cells followed by the imposition of selective conditions as soon as recovery will allow, and before overgrowth by competitors occurs. How well the new systems of timed release[154] of selective agents, following the enhanced repair rates devised by Stephens et al.,[153] will further improve the recovery of damaged and undamaged microbial cells from foods remains to be seen.

Immunomagnetic Separation. Where a targeted species has a specific antigen(s), immunomagnetic separation (IMS) is a useful means of separating it from competitors and food materials allowing various techniques to be used to identify the separated microorganisms (Chapter 63).[33,145] Antibodies used in IMS may be targeted against flagella or somatic antigens. Although the sensitivity of IMS does not allow the reliable or effective capture of low numbers of target microorganisms directly from a food homogenate, it may be used to

- reduce assay time by capturing cells from a pre-enrichment broth and using these to inoculate a selective agar plate and thus avoid the selective enrichment stage[18]
- improve test performance by harvesting target cells from a pre-enrichment broth and inoculating selective enrichment broths[140]
- harvest from a selective enrichment broth for plating onto either selective differential agar media or for use with an alternative method of detection[14,17,90,171]
- aid in salmonella serotyping.[39]

Supermagnetic particles for IMS are available from commercial sources (eg, Dynabeads™, Dynal AS, Oslo, Norway). The particles are available either ready-labeled with attached homologous antibody to a foodborne pathogen, or labeled with antispecies antibody (eg, sheep anti-rabbit) for the subsequent coupling of another capture antibody by the user.[39,53,90]

The use of IMS to harvest *Escherichia coli* O157 from enrichment broths has significantly improved the isolation of this bacterium.[21] Thus, Wright et al.[177] reported a 100-fold increase in sensitivity over the standard method when using Dynabeads labeled with anti-*E. coli* O157 antibodies to detect *E. coli* O157 in minced beef. While IMS has been employed extensively for the isolation of salmonella from foods,[106,138,146,150] Hanai et al.[66] reported that only about 10% of the salmonella cells present in pre-enrichments were recovered by IMS. A high degree of nonspecific binding, particularly to *Citrobacter freundii* and *Enterobacter cloacae*, has been reported to occur on anti-salmonella Dynal™ immunomagnetic beads. Therefore the binding times and washing protocols must be optimized to minimize this effect.[14,34,177] Immunomagnetic separation also has been used to capture listeria from enrichments prior to plating[151] or combined with the Vitek Immunodiagnostic Assay System Enzyme-Linked Immunoassay (VIDAS) technique to detect *Listeria* species.[103] Table 62–8 lists some of the recent reports on the effect of introducing an IMS stage on the performance of traditional and alternative microbiological detection methods.

Table 62–8 Examples of the Improvement in the Detection of Foodborne Pathogens Using Immunomagnetic Separation Followed by Conventional Plating or Alternative Detection Methods

Pathogen	*Food Types*	*Contamination*	*Enrichment*	*Detection Method*	*IMS After*	*Positive Results*		*Reference*

Key to abbreviations:

Methods:

Ab-DEFT = fluorescent antibody staining and epifluorescence microscopy; O/T EHEC = Organon Teknika enterohemorrhagic *Escherichia coli* enzyme linked immunoassay; EIA Foss = Foss automated Salmonella ELISA incorporating immunocapture; PCR-DIANA = polymerase chain reaction—Detection of immobilized amplified nucleic acids

Media:

Broths

m-EC+n = modified EC broth + novobiocin; BPW+VCC = buffered peptone water + vancomycin, cefixime, and cefsoludin; BPW = buffered peptone water; m-BPW = modified buffered peptone water; FB = Fraser broth; $^1/_2$ FB = half strength Fraser broth; m-LEB = modified listeria enrichment broth; m-TSB = modified tryptone soya broth; TSYEB = tryptone soya broth + yeast extract; TSB = tryptone soya broth; M-broth = Manitol broth; RVS = modified Rappaport-Vassiliadis soya broth; UVM I = University of Vermont primary enrichment media

Agars

CT-SMAC = sorbitol MacConkey agar + cefixime and tellurite; MSA-BCIG = MS agar + 5-bromo-4-chloro-3-indolyl-β-D-glucuronic acid; MOX = Oxford agar + moxalactam & colistin sulphate; PALCAM = PALCAM listeria selective agar; BGA = brilliant green agar; XLD = xylose lysine desoxycholate agar

Semisolid Selective Media. Selective motility enrichment techniques (SMET) use the migration of targeted motile (flagellated) bacteria through or over semisolid selective media to isolate them.[156] Test systems can be set up either by using the Craigie tube principle with migration within the agar[31] or by the migration over semisolid medium in a Petri dish.[42] Semisolid selective media are formulated by adding agar or other gelling agents, such as xanthan or alginates, to the selective enrichment medium.[76] The concentration of both the selective agents and the gelling agent is optimized for motility with the possible addition of chemoattractants to enhance performance.[102] Both methods have been exploited for the detection of salmonella.

The Craigie U-tube principle originally was devised to select motile organisms from a poorly motile culture for serotyping purposes.[31] Subsequently, with the addition of antisera, it was used to select clones in the specific phase or nonspecific phase to complete immunological identification of salmonellas based on the Kauffmann-White scheme.[91] Today, the apparatus consists of a test tube or bottle having an inner tube, open at both ends, that is partly immersed in the semisolid growth medium. The device is inoculated inside the inner tube with culture together with appropriate antisera and the motile culture in the opposite phase is recovered from outside the tube.[67] The procedure also enhances antigenic expression. The Craigie tube principle has been used by a number of workers. Harvey and Price advised the use of secondary enrichment through semisolid Nutrient agar as a routine practice to improve the isolation rates of salmonella from clinical, animal, food, and environmental samples;[68,156] colonies from selective agar media were passed through the Craigie tube and plated onto further selective media. Chau and Huang developed semisolid enrichment media from both Rappaport-Vassiliadis medium and a semisolid indicator medium, based on H_2S formation, for screening food samples for the presence of salmonellae.[27] SMET was used by Holbrook et al.[76] to devise a test kit for the detection of salmonella in foods within 42 hours. The kit consisted of a culture vessel containing an elective medium in which were suspended two tubes with porous discs containing different enrichment media in their lower chambers and different indicator media in their upper chambers, both containing a salmonella chemoattractant.[102] The vessel was inoculated with pre-enrichment and after incubation positive tubes were identified by color changes; this test also allowed latex agglutination tests to be carried out directly on the bacteria in the upper chamber.[76]

The use of semisolid selective media in petri dishes has been reported for the isolation of *Campylobacter* species[65] and salmonella from fecal samples, the latter using semisolid Rappaport (SSR) and semisolid selenite medium.[64] De Smedt et al.[42] subsequently evaluated the performance of semisolid modifications to Rappaport-Vassiliadis medium in petri dishes. Evaluation was made using naturally contaminated meat, egg, and cocoa bean samples following pre-enrichment. The optimum formulation modified semisolid Rappaport-Vassiliadis medium (MSRV), containing novobiocin, gave a 39% increase in positive isolations compared with tetrathionate brilliant green enrichment, and could detect <100 salmonella ml^{-1} in the presence of 10^7 other microorganisms ml^{-1}.[43] In a comparison of MSRV with SSR media for the isolation of salmonella from coastal waters, MSRV gave significantly more positives.[129]

Swaminathan et al. first described the use of salmonella antisera-coated discs on semisolid Dulcitol brilliant green novobiocin motility medium to indicate the presence of salmonella by a line of immobilized growth around the disc.[157] Davis and Wray incorporated the antiserum disc into MSRV and recommended inoculating below the semisolid agar surface to form a liquid "bleb" to inhibit the spread of other microorganisms.[38] Many collaborative studies have now been conducted on a range of foodstuffs comparing MSRV against different standard methods.[10,19,43,173]

62.9.2 Solid Media

The gel strength of solid media is not only important for its practical use but it also affects the rate at which nutritional components diffuse to the growing colonies, thus influencing both their size and shape; it must therefore be carefully standardized for use by the manufacturer. The gelling quality of agar is dependent on the source of the natural raw material and the manufacturing process. The optimum concentration of agar for general use is between 1.2% and 2.0%. Solid media in food microbiology have three primary uses:

1. in quantitative methods for enumeration of microorganisms in food samples, using either the spread-plate or pour-plate method or other means of obtaining countable colonies such as by the spiral plate method,[56] the drop plate method (Miles and Misra technique),[29] or the Perifilm™ plate method
2. in qualitative methods by direct streaking of food or environmental samples, or enrichment

cultures or broths onto agar plates or membranes, to obtain separated colonies to find targeted species
3. to obtain pure cultures by the subculture of colonies onto plates for identification purposes.

Quantitative Methods. Counting is done by either the spread-plate or pour-plate method, each having different attributes. The spread-plate method can be used with opaque media and avoids exposing the inoculum to mild heat stress as occurs with the pour-plate method. Many differential features of media may only be well displayed by surface colonies growing under the appropriate aerobic, microaerophilic, or anaerobic conditions. Only a small inoculum, ideally 0.1 ml, can be used on a spread plate in a standard 90 mm petri dish. Where low counts are expected, and to improve detection and precision, larger sample volumes of up to 0.3 ml can be surface plated. Excessive drying of plates prior to inoculation, so that larger volumes are absorbed, is poor practice that can result in significant changes in composition of a medium; also, the risk of colony inhibition by excessive amounts of food debris present from the inoculum must be avoided. Large-size petri dishes can be used to spread up to 1 ml of a food sample.

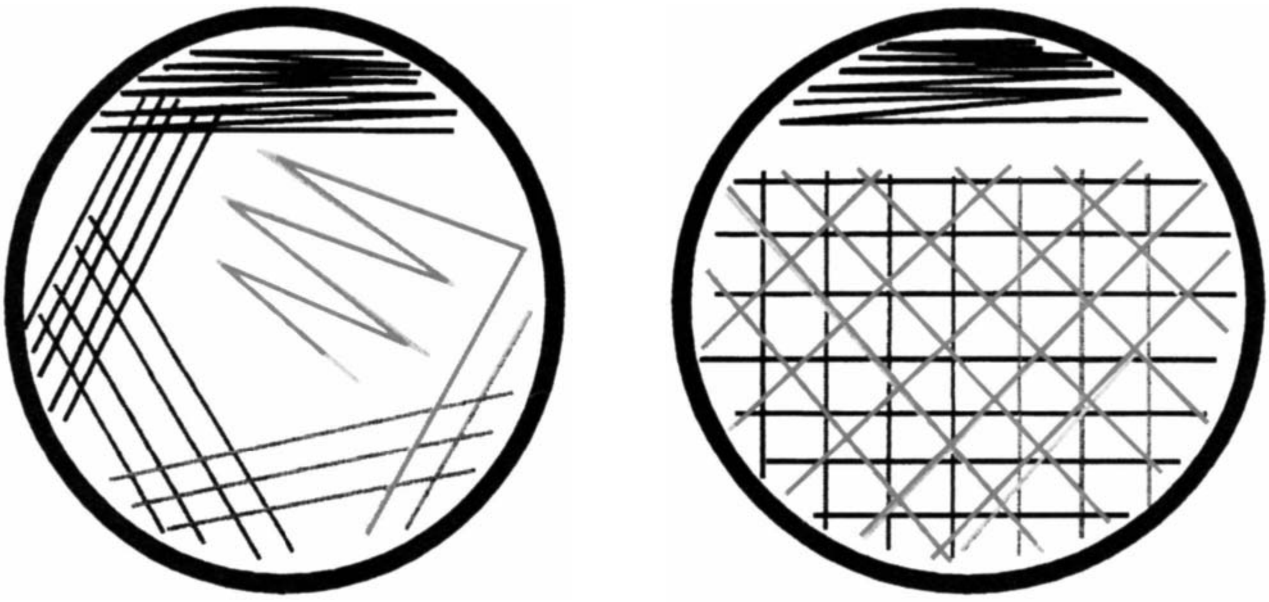
With the pour-plate method, a larger inoculum volume, typically 1 ml, is used in a standard petri dish. Cooling the medium prior to pouring is a critical step and should be monitored reliably. Exposure of the inoculum to molten agar at 45° C to 49° C followed by rapid mixing before cooling to set on a horizontal surface, is generally acceptable for determining counts for mesophilic and thermophilic species. However, for psychrotrophic species a maximum temperature of 47° C is critical for the subsequent growth of some species. It is often good practice to overlay pour plates with a thin layer of the same medium to prevent the spreading of colonies on the surface of pour plates. The inclusion of 0.0005% triphenyltetrazolium chloride to media used in a pour plate can aid the differentiation of bacterial colonies from food particles. The dye is reduced to a red formosan within each colony, giving it a reddish color and aiding observation.[158]

Enumeration may also be made by the spiral-plating method.[56] The apparatus allows an ever-decreasing volume of inoculum to be deposited in the form of an Archemides spiral over the agar medium from the center to the edge of the plate. This procedure allows a range of up to 10^4 cells ml^{-1} to be counted from a single dilution on one plate. Following incubation, colonies are counted using a template that divides the plate successively into quadrants and then into arcs of various length within each quadrant, so that areas containing sufficient numbers of separated colonies can be counted to give a statistically reliable result. The total count is computed from the regions counted.[50,56,127]

It is generally accepted that for total counts, plates containing between 30 and 300 colonies are most suitable for counting on surface and pour plates, this number being reduced to 20 to 150 colonies for the enumeration of indicator organisms and pathogens as nontargeted colonies may also be present. For statistical aspects of such count procedures, see Chapter 60; and for the assessment of test attributes such as sensitivity, linearity, critical level, limit of determination, selectivity, and specificity, see the literature.[3,28,80,81,119,162]

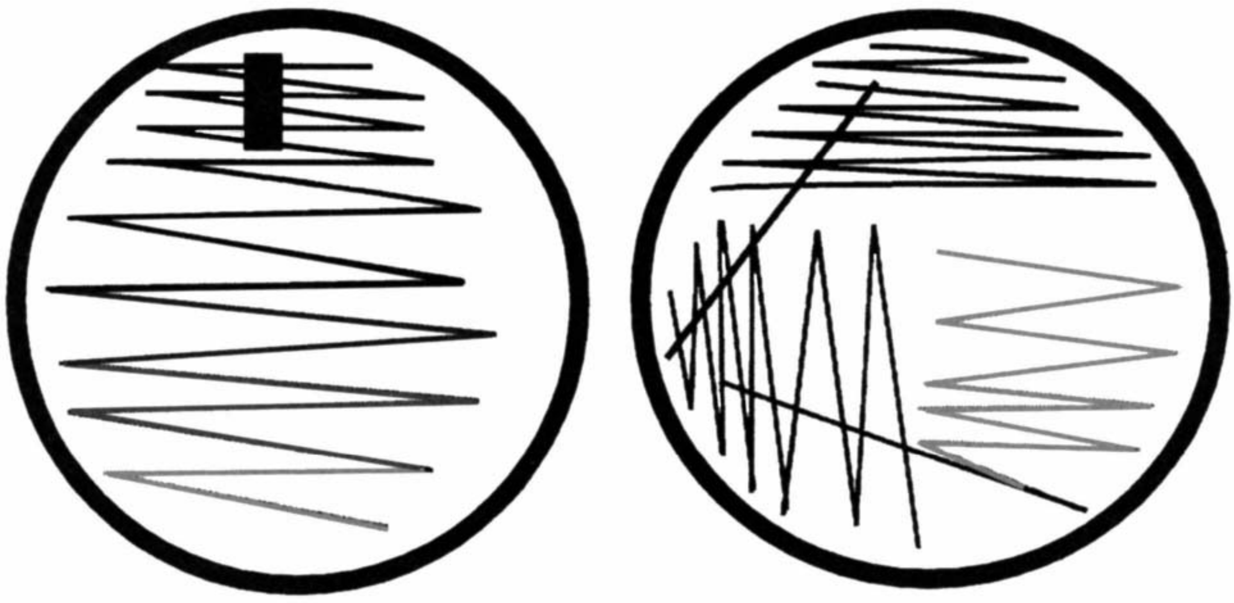
Qualitative Methods. To maximize the chance of isolating the targeted organism from an enrichment broth upon subculture to selective agar, various methods of "streaking out" have been prescribed. The principle is that ever-decreasing numbers of cells are spread over an increasing surface area of the agar to obtain discrete, well-separated colonies that show the features of identification (eg, colony shape and size, color [from pH indicators], hemolysis, proteolysis, lipolysis). The inoculum size, governed by the size of the inoculation loop, is significant and the procedure may be done with or without the sterilization of the loop between each sector. Four methods are compared in Figure 62–2. Method 1 is widely used to check the purity of a culture and comprises five, four, three, then two parallel streaks around the periphery of the petri dish away from the loop unloading area, and then a single tortuous streak over the center of the agar plate. Methods 3 and 4 are of the same principle but use different patterns to give different rates of decreasing density. Method 3 is advocated in ISO Standard 6579, 1997[86] and method 4 in ISO Standard 7218, 1996.[84] Method 2 attempts to achieve a greater distribution of colonies by using the loop to trace away from areas previously inoculated with higher numbers of cells to increase the likelihood of separating the targeted organism from these less favorable cell ratios. For example, methods 1, 2, 3, and 4 gave about 60, <100, 30, and 30 well-separated colonies respectively from the same bacterial suspension.

In all these methods there is a direct relationship between the chance of gaining isolated colonies of the target organism and the numerical ratio it has to the other organisms able to grow on the medium from the inoculum. There is, however, considerable



Method 1.
Widely used method to check a culture for purity by gaining separated colonies.

Method 2.
Repeated streaking across previously inoculated areas to gain greater separation of colonies from dense areas.



Method 3.
Inoculation of selective agars according to ISO Standard 6579, 1997.[86]

Method 4.
Inoculation of selective agars according to ISO Standard 7218, 1996.[84]

personal opinion on the best spreading technique.

Nonselective Agar Media. These media may be formulated with[107,116] or without[24] differential properties or biochemical indicator systems but a detailed examination of the appearance of the colonies as classically described[174] gives some degree of colony differentiation and possible species recognition by an experienced user. Nonselective media used in a qualitative manner are also appropriate for the recovery and growth of injured or attenuated cells.

Selective Agar Media. A comprehensive description of the wide range of selective differential agar media relevant to food microbiology have been described.[30,96] The characteristics of a good selective differential medium include the ability to give typical colonies from a wide range of strains of the targeted organism(s), with maximum inhibition of competitors, and good differentiation from those competitor species not so readily inhibited.[41,71]

Chromogenic Media. New or modified media based on the use of chromogenic and fluorogenic substrates have been developed for the detection, differentiation, or identification of bacteria, yeasts, and molds. These may give faster detection times than conventional procedures. These synthetic substrates are colorless prior to their hydrolysis by specific enzymes. For reviews of the application of fluorogenic and chromogenic substrates in bacterial diagnosis, see the literature.[40,105] The action of the targeted microbial enzyme on a single substrate can achieve much greater specificity than indicator systems based on changes in pH. For this reason, claims have been made that confirmation tests on colonies giving specific substrate reactions in an appropriately selective medium are no longer necessary. Fluorogenic substrates containing coumarin-based derivatives of 4-methylumbelliferyl-β-D-glucuronide (MUG) or 7-amino-4-methylcoumarin (7-AMC) have been incorporated into several media, but as the free fluorochrome is soluble in water and diffuses readily, it is not ideal for use in agar media but very appropriate for liquid media using presence/absence tests or most probable number estimations. Fluorochromes that are easily demonstrated by long-wave UV (366nm) light are available in a range of compounds having different enzyme substrates. MUG is widely used to demonstrate β-D-glucuronidase activity by *E. coli* in lactose broth[58] and lauryl sulphate broth.[48] β-D-glucuronidase activity is present in about 96% of *E. coli* strains,[48,172] but is absent in verocytotoxigenic *E. coli* O157 strains.[160] β-D-glucuronidase activity also is present in some strains of other members of the Enterobacteriaceae, including salmonella (29% of strains), shigella (44%), and Flavobacteria.[59] β-D-galactosidase catalyzes the breakdown of lactose, a feature used to identify coliforms, and 4-methylumbelliferyl-β-D-galactopyranoside (MUGAL) is used as a fluorogenic substrate for this.[15,26] Some other species of the Enterobacteriaceae, including some *Citrobacter* spp., *Enterobacter agglomerans*, and *Serratia marcescens*, while not fermenting lactose, produce galactosidases.[26] Chromogenic substrates that are insoluble or precipitated following hydrolysis are ideal for use in agar media so that color is retained within, or close to, the colony. Strongly colored molecules offer better visualization and discrimination and thereby improve sensitivity. By the appropriate combination of substrates, different enzyme reactions can be demonstrated in the same agar medium, enabling the detection of two or more species or groups at the same time—for example coliforms and *E. coli.* Many new compounds are being synthesized to commercially exploit the value of such chromogenic detection systems; these include 5-bromo-4-chloro-3-indolyl-β-D-galactopyranoside (X-Gal) and 5-bromo-4-chloro-3-indolyl-β-D-glucuronic acid (BCIG).[105]

An example of a medium containing two interacting identification systems is Rambach's agar,[135] which differentiates salmonella colonies from those of other members of the Enterobacteriaceae; selectivity is achieved with sodium desoxycholate. The medium contains propylene glycol, which is used by the majority of salmonella giving a decrease in pH and causing neutral red to be precipitated within the colony giving a "fuchsia" pink color. The inclusion of the chromophore X-Gal distinguishes nonlactose fermenting coliforms from salmonella by producing colonies with a blue color; organisms that use both lactose and propylene glycol give colonies with a violet color, and colonies of those that use neither, such as strains of *Proteus* and other Enterobacteriaceae able to grow on the medium are colorless. However, some less-common but nevertheless important strains of salmonella do not use propylene glycol and thus give false negative reactions. Examples are *Salmonella typhi* and some uncommon strains of *S. paratyphi* A and B, *S. typhimurium*, *S. choleraesuis*, *S. gallinarum*, and *S. dublin.*[94]

62.10 PREPARATION, STORAGE, AND USE OF CULTURE MEDIA

The reliability of bacteriological analysis depends on the correct preparation of culture media, their storage, and use. The following is a list of important

Next Page

aspects of this process.

62.10.1 Recordkeeping

The date of purchase of dehydrated base media and their other components (eg, supplements) should be recorded together with the manufacturer's codes and batch numbers, and their expiration dates. Also record when containers are opened. The rate of use of all media should be monitored so that stock size is proportionate to its rate of use and expiration date. The date of preparation of a batch of medium, sterilization data, and pH measurement should also be recorded together with other physical QA checks, sterility checks, and microbiological assessment data. The expiration date of made-up media, prepared plates, and laboratory-prepared supplements should also be recorded.

62.10.2 Storage of Dehydrated Culture Media, Supplements, and Chemicals

The instructions in the manufacturer's handbook should be followed, including storage conditions (eg, at the recommended temperature and relative humidity and away from sunlight). Media should be used in order of batch number, ensuring that lids are tightly closed after use and should not be used after the expiration date. Powders should be examined before use for any changes in appearance indicating deterioration; any caked, lumpy, or discolored dehydrated material should be discarded. When weighing out, the time that stock powder is exposed to air should be minimized, particularly if the humidity is high.

62.10.3 Water Quality

Freshly prepared distilled or demineralized water should be used and its conductivity measured. Good-quality water should have a resistivity of at least 300,000 Ω cm.[84] Stored, distilled water may have an acid pH due to the absorption of carbon dioxide; this may affect the final pH of weakly buffered media reconstituted from dehydrated material. Water from stills containing visible algal growth or processed water that is turbid should not be used. Demineralized water can become heavily contaminated with bacteria from the ion-exchange apparatus. These bacteria may produce heat-stable substances that are inhibitory to the growth of other microorganisms so ion-exchange columns should be used in accordance with the maker's instructions, and if recommended, regularly decontaminated.

62.10.4 Media Preparation

For commercial media, the manufacturer's instructions should be followed closely. A face mask should be worn, and preferably there should be an air-extract system over the work areas to minimize the inhalation of dehydrated powders. Contact of powders with the skin should be avoided. Media should be prepared in a vessel large enough to allow good mixing and rapid heating and, in the case of media containing agar granules, time should be allowed for the agar to swell before heating to dissolve. The pH of most commercial media is adjusted by the maker so that after sterilization, the pH is correct; therefore the pH should only be adjusted prior to sterilization if instructed to do so. If the pH is wrong after sterilization, the pH of the water used should be checked. The quality of most media deteriorates during exposure to heat; therefore, this should be minimized. Excessive heating of media can cause destruction of nutrients, pH drift, precipitation, weakened gel strength, and change in color, all leading to poor bacteriological performance. Autoclaves should be properly maintained and serviced by trained engineers, and thermal locks should be fitted to prevent the door being opened until the chamber temperature is below 80° C. They should have pressure gauges and a calibrated thermocouple fitted into the exhaust line, each attached to a recorder so that the temperature and pressure cycles are recorded; records should be kept. Either thermocouples within the load or indicator tapes attached to containers or baskets should be used routinely to demonstrate that a sterilizing cycle has been completed. The use of agar preparators is recommended as these are designed to minimize the exposure of the media to heat during melting of the agar and sterilization, and thus provide media of a better and more consistent quality.

Storage of Prepared Stock Media. Prepared stock media differ in their shelf life according to either the inventor's or manufacturer's recommendations. If medium is not used on the day of preparation, and there is evidence that deterioration will not occur, it should be stored in the dark at 2° to 8° C for no longer than the recommended time. Liquid media should be dispensed in sealable containers to prevent water loss and contamination. Plates of agar media should not be dried and then stored at chill temperature, as this will cause excessive hysteresis resulting in concentration of the media components and possible inhibitory effects on bacterial growth. Also, unless such plates are poured and dried in an ultraclean environment (eg, a laminar flow cabinet), they are likely to become contaminated.

Preparation for Use. The time for reheating of agar-based products should be minimized. Agar media should be cooled to 45° C to 48° C by immersion in clean water in a disinfected water bath with the water level just above that of the agar in the bottle, before addition of supplements or the pouring of agar plates. Chill-stored supplements should be brought to room temperature before opening/rehydration and/or use and handled with care; antibiotic powders can cause hypersensitivity to the user. Soluble supplements must be completely dissolved after addition of the required solvent (eg, sterile water, alcohol) and mixed well. Insoluble supplements should be homogenized before adding to the base media. Molten agar media should be used within 3 hours of cooling. Antibiotic solutions at use concentrations should not be stored for future use.

Pouring of Agar Plates. Supplements are added to the molten cool base, mixed well without generating excessive foaming, and immediately poured. Techniques are necessary that avoid extraneous contamination, and the process should take place preferably within a laminar flow cabinet. If the medium is too hot when poured, excessive condensation results. The outside of each bottle taken from the cooling bath should be wiped before pouring the medium from it. The correct volume should be poured into each dish. Media should be allowed to solidify quickly in the horizontal position and dried for a minimal time, to remove surface moisture, thus avoiding concentration of components. Exposure to sunlight should be minimized.[170] An automated system is useful for large numbers of plates.

62.11 QUALITY ASSURANCE OF CULTURE MEDIA

62.11.1 The Manufacturer's Role

Commercially manufactured dehydrated media and supplements undergo extensive quality control by the producer. This may include the testing and selection of raw materials against chemical and/or microbiological specifications, then production against standard operating procedures, following Good Manufacturing Practices (GMP) guidelines[108] and/or in compliance with documentation prepared and accredited to ISO 9000. The end-product undergoes physical evaluation and qualitative and quantitative microbiological assessment, using appropriate test strains to ensure performance to set quality standards.[108] This process is essential because of the variability that can occur in the composition of the individual nutrient components of the medium, as discussed previously, and to provide proof of media quality for internal control and/or for certification purposes.

62.11.2 The Laboratory User

Physical Tests. These include simple examination for color, clarity, pH at 20° C to 25° C, accuracy of dispensed volumes, and, for agar media, assessment of gel strength.[35]

Microbiological Tests. While it should not be necessary for the laboratory to consider repeating the extensive testing of the manufacturer, minimal testing of a qualitative or quantitative nature should relate to the proposed use of the medium and the laboratory's need for validation of performance. A minimum range of testing might include sterility checks on all media; for commercially prepared (certified) ready-to-use poured plates, inoculation in a qualitative manner with a suitable test organism on each day of use; and for laboratory-prepared liquid media, inoculation with the final two dilutions of a simple dilution to extinction series[139] of one strain and comparison of the count obtained with a suitable control. For selective liquid media, the isolation of the targeted species from a low (<10 cells) inoculum in a mixed culture of suitable competitor organisms, with or without added sterile food is appropriate. For agar media apply tests, preferably by a quantitative method, it is necessary to demonstrate that the medium supports the growth of a small inoculum of a robust target strain and also a more sensitive target stain, and that each produces the correct reactions and/or typical colony shape and size; and where appropriate, that the agar suppresses the growth of a readily inhibited nontarget organism and gives a negative response with a less well-inhibited strain.[30] For quantitative tests on agar plates, the most efficient method of analysis is use of the spiral-plate method,[56] but other methods (eg, the Miles and Misra [drop] technique[29] or the use of the ecometric plating method[114]) by skilled operators are further options.[30]

For new stock media and supplements with new batch numbers, testing should be carried out to confirm performance, either against a previous batch or against a "gold standard," to ensure the batch has an acceptable performance. When purchasing a large amount, testing of a batch prior to confirming an order may be considered. This testing would be done using a wider selection of positive and negative strains to measure the quantitative recovery of the target microorganism and the quantitative inhibition of selected competitor organisms, together with confirmation of the expected colony reactions. It can also be appropriate to undertake further testing to demonstrate that the batch is "fit for its intended use." For example, if the medium is required to detect the presence of stressed cells from processed food, and the medium is formulated to recover such cells, then this should be experimentally demonstrated. It may also be appropriate in the case of liquid media to assess, on at least one occasion, the growth rate of a targeted organism. When establishing the performance of media prepared in the laboratory from individual components, sufficient testing using protocols that validate the significant characteristics and attributes of the medium may well be appropriate.[30]

There are currently no international standard or guidance documents concerning the QA validation procedures for media used in food microbiology; therefore, some small degree of variation in the standard of performance of media from one supplier to another is to be expected. Within Europe, the European Standardization Committee (CEN TC275 Food Analysis) is preparing a guidance document for "Quality assessment and performance testing of culture media."

62.11.3 Test Strains and Methods

How well a prepared batch of medium is assessed depends on the characteristics of the test strain(s) chosen and the methods of testing. Experience within a laboratory can identify robust and sensitive targeted and nontargeted strains appropriate for each medium used. Occasionally the "inventors" of new media identify and recommend the use of particular strains; the use of such strains improves validation of media performance.[73] Robust target test strains that grow well may not readily show small deficiencies that retard the growth of more sensitive targeted strains, and robust competitor strains that grow well may not show a deficiency in selectivity, whereas the increased growth of sensitive nontargeted strains will do so. Manufacturers use a selection of test strains for each medium to meet the quality requirements for medical, food, agricultural, and other purposes. Many of these strains are housed in national culture collections. For example, for quality assessment and accreditation needs, the UK National Collection of Type Cultures at the Central Public Health Laboratory (Colindale, London, England) have available reference collections for testing media for use with general foods, dairy, water, and food spoilage. Most of the test strains recommended by the International Committee on Food Microbiology and Hygiene[35] are available in "test strip" format from the National Collections of Industrial and Marine Bacteria (Aberdeen, Scotland). However, many of these strains are not of food origin or were not originally isolated using microbiological methods used for foods. It is, therefore, appropriate to supplement these test strains with well-characterized recent isolates that have been maintained in a stable state (eg, freeze dried, or stored at –70° C or lower) and have only been subcultured a few times, so that the opportunity for phenotypic alteration has been minimal.[152] Standardization of the methods of maintaining, preparing, and using cultures for culture media assessment have been proposed by the European Cooperation for Accreditation of Laboratories.[46]

62.12 ACCREDITATION, VALIDATION, AND PROFICIENCY TESTING

62.12.1 Accreditation

It is now recognized internationally that for a laboratory to produce consistently reliable data, it must implement an appropriate program of quality assurance measures[147,155] that is recognized by the process of accreditation of the laboratory.[5] Within the European Community, member states are progressing toward a common validation procedure,[46] which in the United Kingdom (UK) is operated by the UK Accreditation Service (UKAS) provided by the National Physical Laboratory of the Department of Trade. The European Standards, EN 45000 series for testing laboratories,[118] stipulate the steps that analytical (microbiological) laboratories must take to acquire accreditation. The UKAS accreditation procedure to these standards is outlined in guidance documents.[118] These require that, for accreditation, a laboratory must produce a quality manual and a quality policy statement. The manual must contain and describe in detail the laboratory's scope of testing or analysis and describe the quality system, organization, the roles of related management, lines of communication, and the job descriptions of relevant senior staff, together with their qualifications and training. The functions of the quality manager with respect to quality audits, quality system reviews, and audit reports also must be given. The accreditation process also concerns the use, calibration, and traceability (to national standards) of physical measurements such as time and temperature, and the maintenance and use records of all equipment that is used in the laboratory's accredited methods. Methods of analysis must be fully documented and validation data provided. The laboratory facilities, maintenance, and working environment for the staff—particularly of any specialized areas—must also be documented. UKAS requires that staff are trained and must demonstrate that they are technically competent for the work they carry out. The laboratory also is required to operate an internal quality control scheme, to monitor the performance of individual microbiologists, and to participate in external proficiency testing schemes.

Laboratories may use national or internationally prescribed methods (eg, ISO Standards), alternative methods,[45] or "in-house" methods. All, however, must have a degree of validation adequate for the purpose of use. That is measurement of repeatability, reproducibility, specificity, sensitivity, and limit of detection by interlaboratory trials—thus the precision of the method is documented. The absolute accuracy of a method is not, however, the objective.[45]

62.12.2 Validation Methods

Many well-established ISO standards for the microbiological examination of food and animal feeding stuffs currently lack precision data on interlaboratory performance but are acceptable on the grounds that the methods have stood the test of time prior to standardization. However, more recently devised methods, particularly for the detection of the emerging pathogens, do not have such status. Before an ISO Standard can become a European Committee for Standardization (CEN) standard, performance data, and particularly the reproducibility and repeatability of the method, must be known and incorporated into the text. Under the Fourth Measurement and Testing program of the EC/DG XII, a validation program, "Evaluation of Microbiological Methods for Detection and Enumeration of Microbiological Contaminants in Foods," will generate the necessary performance data on ISO and CEN methods for the detection of *Salmonella* species, *Listeria monocytogenes*, and *Escherichia coli* and enumeration methods for *Bacillus cereus*, *Clostridium perfringens*, and *Listeria monocytogenes*.

Alternative microbiological methods (ie, manufactured kits) based on more recent technologies claim various advantages over traditional methods, such as speed of analysis, less expertise required, less hands-on-time, and automatability. For acceptance, these also require validation status. International organizations such as Associattion of Official Analytical Chemists (AOAC) International,[4,111] the International Dairy Federation, the Nordic Standards Organization (NMKL), and national schemes such as the French Standards body (AFNOR)[98] have in place suitable validation protocols and operational mechanisms for assessing such kits. The AOAC has a proven track record for both traditional and alternative methods[4] and is used by the US Food and Drug Administration (FDA) for this purpose. Under present development is a European-wide validation certification scheme—MicroVal. This will operate to a European CEN Standard—"Microbiology of food and animal feeding stuffs. Protocol for the validation of alternative methods," which is in preparation, uses validation data and statistical analyses produced by MicroVal pretrials.[45,137]

62.12.3 Proficiency Testing

The objective of external proficiency testing schemes is to measure a laboratory's performance of analysis using blind samples prepared by an external organization. The results are confidential but indicate the ratings of each participating laboratory. Samples relevant to the work of the laboratory are sent at predetermined times for analysis and the reported data analyzed by the organizers. In the UK, such schemes are run by the Public Health Laboratory Service (Central Public Health Laboratory, Colindale, London). The Food External Quality Assurance Scheme (EQAS) provides freeze-dried materials for five different purposes. These are for the Standard Scheme, detecting foodborne pathogens in samples; an Extended Standard Scheme of qualitative and quantitative methods where the operator decides from a given scenario which tests to perform; and three further schemes specific for shellfish, dairy, and water analysis. The UK Ministry of Agriculture Fisheries and Foods, through its Central Science Laboratories (York, England), operates a "Food Examination Performance Assessment Scheme" (FEPAS), providing verified blind samples of various dried meats containing target and competitive flora; again the results are confidential and provide independent proof of the quality of analysis achieved. Reference materials,[12] made at the Netherlands National Institute of Public Health and Environmental Protection (Bilthoven, The Netherlands), comprise gelatin capsules of dried milk powder containing high or low levels of relevant foodborne pathogens (eg, *Salmonella* species, *Listeria monocytogenes*, *E. coli* O157). These are used by addition to any foods with their own natural microbial flora. The gelatin capsules, being stable for several weeks and having naturally stressed cells from the preparation procedure, have been used in several European trials on the interlaboratory validation of methods.[10,88] Sources of reference materials for proficiency testing are available in a number of further countries. The International Dairy Federation has a standard for the assessment of analyst performance doing colony counts.[81]

62.13 CONCLUDING REMARKS

The microbiological analysis of foods is becoming far more formalized and thus less flexible, particularly in Europe, as implied in the latter parts of this text and elsewhere. While standardization of methods, accreditation of laboratories, and proficiency testing leads, hopefully, to our goal of improved reliability and a more uniform quality of analysis, will it also retard or even stifle future advances in methodology? It is inevitable that adoption of a new method will be slow. It will also be increasingly expensive to validate its performance and this will be a significant barrier to the wide adoption of a new method.

Traditional methods are criticized for being labor-intensive, slow, and requiring a reasonable level of expertise and/or experience for their proper performance and interpretation. Yet in the past 30 years, no alternative analytical method has completely, or even in a significant part, replaced them. Is the needle in the haystack (or the one pathogenic *E. coli* cell in a raw meat sample) just too elusive for methods other than those which rely on some form of growth stage prior to detection?[77] ELISA, although increasingly used as a means of speeding up microbiological analyses, has not eliminated the need for this growth stage. Will gene probes be more successful and will more sensitive direct detection methods, which may not be confirmable by traditional microbiological methods, be accepted as evidence of the presence of an undesirable microorganism, recognizing the increasing evidence that our existing media fail to detect severely injured and stressed microorganisms?[153] In the meantime, the traditionalists progress by reformulation of existing microbiological media, with an occasional new idea that makes a significant breakthrough. Such developments will continue with the dual aim of making our methods more robust and sensitive.

63.1 INTRODUCTION

Immunological techniques historically have been used by microbiologists and pathologists for the direct and indirect detection of microbial pathogens. The high sensitivity and very high specificity of these methods can give very accurate and rapid results. In food microbiology, the main application is in the detection of microorganisms, their structural components, or toxins. Pathogenic microorganisms may occur in foods in numbers that are far below the sensitivity of any immunoassay technology. For this reason pre-enrichment and/or enrichment culture (see Chapter 62) usually is necessary prior to the use of immunological tests. This chapter describes the use of immunological techniques for the detection of microorganisms and their toxins in foods and in cultures.

63.2 MICROBIAL ANTIGENS

Antigens from bacteria may be divided into three main types according to their location: (1) those present on the cell surface and readily accessible to antibody reactions such as the O (somatic), H (flagella), K (capsule), fimbriae, and outer membrane proteins; (2) those hidden within the cell wall or deeper and inaccessible in intact organisms to antibody reactions; and (3) those exported by the bacterial cell such as bacteriocins and exotoxins.

63.2.1 O Antigens

O antigens are present in the cell wall of bacteria and are lipopolysaccharide (LPS) in nature. They are heat-stable, resistant to alcohol, and resistant to acid but destroyed by periodate treatment. Phenol or formaldehyde treatment may inhibit O agglutination. O antigens can undergo smooth to rough transformation. This is a gradual process during repeated subculture and may cause a granular pattern of growth in broth culture and changes in serology. The reaction between smooth organisms and specific O-antiserum results in a granular type of agglutination. Autoagglutinating strains may be alcohol- and heat-treated before O serotyping. LPS, found typically in the Enterobacteriaceae, are complex molecules composed of three distinct moieties, a lipid component, a core oligosaccharide, and a side chain that confers the O serotype specificity. The core oligosaccharide in most of the Enterobacteriaceae comprises heptose and 2-keto-3-deoxyoctonate (KDO).

63.2.2 H Antigens

These are flagella proteins. They are heat-labile, acid-labile, and are detached and eventually inactivated by alcohol. They are stabilized and remain immunogenic and antigenic after treatment with formaldehyde. Loss of flagellae in a culture renders the organisms nonmotile and nonagglutinable in specific H antisera. The flagella antigen reaction with antiserum produces a looser, fluffier agglutination than that produced by O antigens. Phase variation occurs in salmonellae, designating Salmonella H antigenic types into either phase 1 or phase 2. Complete serotyping may involve phase-changing techniques involving the use of phase-specific antisera. The major protein component of flagella is flagellin. For example, the flagellin protein of the H:7 antigen often associated with *Escherichia coli* serogroup O157 has a molecular weight of approximately 66kD.[96] H antigens are usually highly immunogenic and H-sera is typically high-titered and of high affinity.

63.2.3 K Antigens

K antigens are capsular polysaccharides. They can be removed from the organism by heat treatment, although they are not considered particularly heat labile. Isolates may be serotyped with K-specific antisera, but this tends to be a procedure for a specialized laboratory. K antigens can inhibit the somatic O-antigen reaction and therefore it may be necessary to use heat treatment to allow O serotyping. *Salmonella typhi* possesses the Vi capsular antigen, which is heat-stable but easily removed from the cell surface by heat treatment, thus allowing O serotyping. Agglutination of unheated organisms by Vi-specific antiserum is a presumptive identification of *S. typhi.*

63.2.4 Fimbrial Antigens

Fimbriae (pili) are bacterial appendages similar to flagella but smaller and shorter. Nonfimbriate to fimbriate and fimbriate to nonfimbriate conversions may occur in cultures; this is often related to subculturing practices. In food and veterinary microbiology, detection of the fimbrial type SEF 14 of *Salmonella enteritidis* and *Salmonella dublin* is now possible using a commercially available latex agglutination kit.[111]

63.2.5 Outer Membrane Proteins (OMP)

OMP are a heterogeneous group of proteins found within the cell wall and may be closely associated with the LPS components. Some OMP are porins and some are formed in response to starvation. All surface-located OMP are potential targets for antibody reactions.

63.2.6 Toxins

Toxins may be intracellular or extracellular and have potent biological activity. They vary in their heat- and chemical-stability and therefore some toxins may survive the cooking process. Detection of a number of toxins in food and culture has been achieved through animal feeding studies, cell culture, and immunoassay. Immunoassay may be performed on the food sample or on cultures of organisms isolated from the food. Specific treatments such as polymyxin B and lincomycin can be used to increase the production or release of toxin.[13,15]

Mycotoxins are produced by fungi via the polyketide route as secondary metabolites. A large number of mold species produce these toxins with many designated as carcinogenic. Highly potent mycotoxins produced by some strains of *Aspergillus flavus* and *Aspergillus parasiticus* are designated aflatoxin. Mycotoxin levels in food may be measured using enzyme-linked immunosorbent assay (ELISA) tests or separation and concentration for subsequent analysis may be effected using immunoaffinity columns; see also Chapter 53.

63.2.7 Fungi

The major antigens found in fungi are extracellular polysaccharides (EPS). Large quantities of EPS are produced during fungal growth in food and culture and these may be detected easily by immunoassay. The EPS of *Aspergillus* spp. and *Penicillium* spp. in common with many other fungal species consist of galactomannan. The immunodominant epitope of galactomannan is the β(1,5)-linked D-galactofuranosyl side chain.

63.2.8 Viruses

Foodborne outbreaks of viral gastroenteritis are becoming more common. The types of virus implicated include hepatitis A, adenovirus, rotavirus, and small, round, structured viruses (SRSV), including the Norwalk virus and astrovirus. Viruses contain a single nucleic acid type, either DNA or RNA. The protein or glycoprotein coat (capsid) is composed of capsomeres, which are individual protein units. Viruses also may possess a lipid membrane derived from host tissues in which viral proteins may be found in the form of spikes (peplomers). Antisera for immunodiagnostic use may be prepared against the exposed proteins and glycoproteins. Antigenic changes occur frequently in viruses, which may affect their detection. Both antigenic drift (slight change) and antigenic shift (major change) are known to occur. Viral contamination of food is generally at a level lower than detectable by immunoassay. Success has been achieved, however, in detection of virus in shellfish and aquatic bivalve mollusks that as filter feeders may concentrate virus many hundreds of times.[26] In most investigations, culture of the sample in susceptible cell lines followed immunoassay or some other test was required (see Chapter 52).

The viral capsid proteins provide the main target for specific antibody reactions. Although some direct immunoassays exist for the detection of viruses in clinical specimens, the sensitivity of such tests is too low for use in detecting foodborne viruses. Antibody may, however, be used to capture virus particles for subsequent analysis by non-immunoassay methods (see Section 63.6).

63.2.9 Protozoa

Parasitic protozoa such as *Toxoplasma, Cyclospora, Giardia, Sarcocystis,* and *Cryptosporidium* have been implicated in outbreaks of foodborne illnesses (see Chapter 51). They have complicated surface antigenicity. Due to low numbers encountered in food, the analysis for parasites generally is limited to microscopical techniques. Fluorescent antibody techniques may have a role and are currently used in detection of some protozoa in environmental samples.[88]

63.3 ANTIBODY PRODUCTION

63.3.1 General Aspects

The production of antibodies is a result of challenge to the animal of a foreign substance or substances. Natural antibody responses are a result of microbial infection or sometimes a localized chemical challenge such as certain food components. A molecular species that is used to induce an immune response in an animal is known as an immunogen. A molecule must be recognized as nonself to induce an immune response and must be presented in a suitable form and at a suitable location. An immunogen must be of a certain minimum molecular weight (approximately 5000) to induce a response. However, the actual areas on the molecule that are recognized by the immune system are relatively small and may consist of as few as three amino acids in the case of protein antigens. These regions are known as epitopes; a large and complex protein may have a number of different as well as related epitopes. The majority of epitopes are discontinuous (ie, consist of amino acids that are contiguous only in the folded tertiary or quaternary structure). The precise regions on the antibody molecules that bind to the antigen epitope are known as the paratopes and these are located at the Fab end.

Five different immunoglobulin isotypes have been identified in mammals: IgG, IgM, IgA, IgD, and IgE. Of these, only IgG and IgM have found an important role in immunodiagnostic tests for the detection of microbial antigens. The primary response to the introduction of an immunogen, either naturally by infection or artificially, may result in a limited number of antibody-producing clones of lymphocytes. As the infection proceeds, the number of clones increases, leading to a pool of circulating antibodies with a diverse range of reactivity. Each of the clones will, however, produce antibody with very specific reactivity toward a single epitope. The response of an animal to a microorganism thus may consist of the production of antibodies against a wide variety of epitopes, and the response will vary between animals. IgM is the predominant antibody in early infection. Later, or in subsequent challenges with the same organism, IgG predominates.

63.3.2 Polyclonal and Monoclonal Antibodies

The antibody produced by a single clone of lymphocytes will be consistent in affinity and avidity, always reacting with a single epitope. In 1975, Kohler and Milstein[53] succeeded in immortalizing single clones of antibody-producing mouse cells by fusing them with mouse lymphoma cells and growing them in sufficient volume where usable quantities of antibody could be prepared. This type of antibody derived from hybridoma cells is known as monoclonal antibody. The technique of producing monoclonal antibodies is highly advanced and there are a variety of methods to develop the clones and for the large-scale culture and purification of the antibody. Diagnostic tests that had previously relied on polyclonal antibodies could now use the superior specificity of monoclonal antibodies that also offer the advantages of worldwide assay standardization. Despite the increasing use of monoclonal antibodies in diagnostic test kits, there are still many, particularly in food microbiology, who use polyclonal antibodies. This is due, in part, to the high affinity and avidity of polyclonals and their clonal diversity.[46] These properties can be advantageous for microorganisms that exhibit antigenic diversity because some isolates may have reduced reactivity against a single epitope-reactive antibody. Usually, high-affinity antibodies yield better sensitivities than low-affinity antibodies.[69]

63.3.3 Antibody Form and Function

Immunoglobulin G (IgG) is a glycoprotein of approximately 150kD in molecular weight and is the most abundant immunoglobulin in mammalian serum, amounting to between about 12 and 20 mg ml^{-1}. The IgG molecule (Figure 63–1) consists of two identical heterodimers, each composed of a heavy and light chain. The heterodimers are linked by a disulfide bridge known as the hinge region. Each heavy chain consists of one variable and three constant domains. The light chains are composed of one variable and one constant domain. The variable regions that give the antibody specificity are located at the top of the Y-shaped structure; this end is known as the fragment antigen binding (Fab) region.

At the other end of the IgG molecule is the fragment crystallizable (Fc) region. This is recognized by host defense mechanisms including binding to cells of the immune system and to C1q, the first component of the complement system. It also is bound by the surface proteins of certain microorganisms, most notably Protein A from *Staphylococcus aureus* and Protein G from Lancefield group G streptococci.

The structure of IgM is similar but it is a pentamer having 10 antigen-combining sites and a molecular weight of 950kD. As with IgG, the IgM subunits are linked by disulfide bonds but also have the addition of a protein J (joining) chain. Some IgM may be in hexameric form lacking the J chain. Certain oligosaccharides are associated with IgM.

The specific binding of antibody does not cause direct harm to microorganisms but does allow host effector mechanisms to operate, of which the most important is the activation of the complement enzyme cascade system. This results in direct toxicity of complement components on bacteria as well as a localized inflammatory response leading to many defensive effects, including migration of phagocytic neutrophils and monocytes, release of opsonins for phagocyte stimulation, mast cell degranulation causing the release of histamine, and the release of

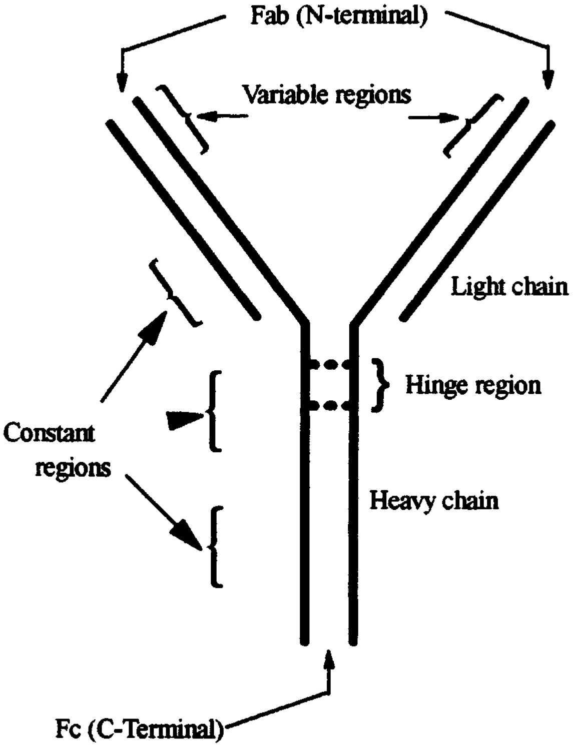

Figure 63–1 IgG Molecule. The IgG molecule has two light chains and two heavy chains attached at the hinge region. Antigen binding occurs at the N-terminal end, Fab (fragment antigen binding), which is in the variable region. The Fc (fragment crystallizable) region occurs at the C-terminal end in the constant region.

bacterial proteases. Other specific effects of antibody on bacteria may include immobilization due to the cross linking of flagella.

Antibody binds to antigen by a number of noncovalent forces at the molecular level. These forces are hydrogen bonding, electrostatic, Van der Waals, and hydrophobic. For these forces to effect binding, the epitope and paratope must be in very close proximity; this therefore requires both to have a complementary shape. From this, it follows that shapes and chemical groupings that are less complementary result in lower affinity attachment. The number and type of molecules that form the epitope also are important in defining the strength of attraction. Epitopes showing minor variations will bind to greater or lesser extents. Homogenous epitopes and complementary paratopes will give maximum binding for that configuration.

63.4 THE APPLICATION OF IMMUNOLOGICAL TECHNIQUES IN FOOD MICROBIOLOGY

In the detection of microbial antigens using antibodies, the key feature used in all tests is the specific binding of antigen and antibody. The differences between the wide variety of available assays are the methods of detection of that binding. No immunoassay formats have been specifically designed for food microbiology, but a number of methods have been adapted for this use. Each immunoassay has its own requirements, advantages, and disadvantages according to its application—whether for food microbiology or otherwise. Table 63–1 illustrates the range of sensitivity of several immunological methods used to detect the enterotoxins of *Staphylococcus aureus*, *Clostridium perfringens*, and the botulinum toxin of *Clostridium botulinum*.

Many of the other available immunoassay technologies could probably be extended for use in food microbiology.

63.4.1 Classification of Immunological Techniques

Immunological techniques include immunoassays for detection and assay of biological molecules; they include the use of antibodies as tools for capture and for the concentration of microorganisms prior to detection or culture. They also have a significant role in research for characterization of organisms and antigens. Immunological techniques may be divided into several groups. Those described here are the ones most used in immunoassays and include other methods that are not strictly immunoassays, but that use antibodies and are useful in food microbiology. A more comprehensive listing and classification has been compiled by Price and Newman.[79]

63.4.2 Immunoassay Methods

The term immunoassay is used here in its broadest sense and includes those tests used for qualitative results (ie, yes/no) as well as those used quantitatively. Quantitative immunoassays determine the amount of antigen detected in a sample, which can be used, for example, to determine the level of mi-

Table 63–1 Comparisons of the Limits of Detection of Various Immunological Methods for the Demonstration of Bacterial Food Poisoning Toxins

Immunological Method	*Staphylococcal Enterotoxins A & B µg ml⁻¹*	*Botulinum Toxin Type A Mouse 50% Lethal Doses ml⁻¹*	Clostridium perfringens *Type A Toxin µg ml⁻¹*

Enzyme-linked immunoassay	0.001	10	0.000001

crobial toxin(s) in a food sample. Most of the available assays give qualitative results by giving either a simple positive or negative signal or by determining whether the result is above or below a specified value. Divisions in immunoassay type may be made between reagent-limited (generally competitive) and reagent-excess (immunometric). A division also may be made between homogenous and heterogenous assays. In homogeneous immunoassays, the test sample antigen and reagent antibody are mixed to bring the antigen and antibody together; there is no separation of free from bound reagents. The result is then obtained directly. These immunoassay techniques include some of the oldest and most simple tests, such as agglutination and precipitation. The limited number of steps, short reaction times, and relatively low cost make them popular methods in many microbiology applications. Heterogeneous immunoassays account for most of the immunology-based diagnostics used today. After reaction of the test sample and reagents, one or more steps are used to separate the free unreacted label from the bound label. The requirement for separation steps generally leads to longer assay times than in homogenous tests but the separation of free label from bound label gives better potential for high sensitivity and the removal of the food matrix during the process can improve, and is often essential for, specificity. By separating each of the reaction and detection stages, the development of such tests is simplified, with common reagents being used for a number of related assays. ELISA is the most common example of heterogenous immunoassays.

Heterogeneous immunoassays may be divided further into immunometric (reagent-excess) and competitive (reagent-limited) types. In an immunometric assay, there is a capture step, generally employing a specific antibody. Antigen present in the test sample binds onto this capture antibody and a labeled antibody is added. The detection of binding of this labeled antibody determines the result of the reaction. An increasing level of signal is indicative of an increasing quantity of analyte in a direct relationship. Competitive immunoassays use a labeled (tracer) antigen that competes with the sample antigen for binding to a (generally) solid-phase antibody. In a competitive assay, the signal level is reduced by increased concentrations of the antigen in the sample because this sample antigen allows less tracer antigen to bind to the solid-phase antibody. Alternatively, a solid-phase immobilized antigen is used to capture labeled antibody in the presence of sample antigen. If antigen is present in the sample in sufficient quantity, it binds to the labeled antibody, thus stopping it binding to the solid phase. Labeled antibody is therefore removed in the washes, thus reducing the signal strength after substrate addition.

Antibodies, like many other proteins, may be attached easily to solid surfaces and thus provide an effective means for capturing homologous antigen molecules. Washing the surface then removes unbound material, including excess antigen, other antigens, and irrelevant or interfering matrix material. If it is multivalent (more than one antibody binding site), the bound antigen can react with further antibodies. The second antibody, when linked with an indicator molecule to form a conjugate, will show whether it bound and therefore whether the target antigen was present originally. In this immunometric, heterogenous type immunoassay, an excess amount of the anti-analyte reactants is desirable. A large excess of solid-phase antibody can bind a large amount of target antigen. A large excess of the second tracer antibody will then be more likely to saturate the bound analyte. With a fully saturated system, the signal generated will be at a maximum and, within the designed working range, will correlate with the quantity of bound antigen.

The labels used to prepare the indicator antibodies include radioactive isotopes, enzymes, fluorophores, chemiluminescent molecules, and small particles. Enzyme labels commonly used are listed in Table 63–2. The substrates that produce a soluble reaction product are used in visual and instrument-read assays. The precipitating substrates produce insoluble colored reaction products and may be used for membrane-based diagnostics including immunochromatography, dot-blots, and for visually read ELISA tests.

63.4.3 Detection of Reactions

The majority of homogeneous assays, especially of the agglutination type, are read visually or by nephelometry. Heterogenous assays frequently, but not exclusively, use instruments for reading of results. Modern immunochromatography tests are examples of immunometric, heterogeneous, visually read tests. Enzyme immunoassay (EIA) reactions produce a colored result and, although it is sometimes possible to read by eye, greater low-end precision is obtained by a spectrophotometric measurement. Both fluorescence immunoassays (FIA) and chemiluminescent immunoassays (CLIA) produce a light output at specific wavelengths with FIA requiring excitation light. Both of these methods require instrumentation that therefore enables quantitative mea-

Table 63–2 Enzyme Labels and Substrate Systems Commonly Used

Enzyme Label	*Substrate*	*Reaction Product*	*Use*
Horseradish peroxidase	O-phenylenediamine (OPD)	Soluble	ELISA
	2,2'-azino-bis-(3-ethylbenzothiazoline-6-sulphonic acid) (ABTS)	Soluble	ELISA
	3,3',5,5'-Tetramethylbenzidine (TMB)	Soluble	ELISA
	3,3'-Diaminobenzidine tetrahydrochloride (DAB)	Insoluble	Immunoblotting
	3-Amino-9-ethylcarbazole (AEC)	Insoluble	Immunoblotting
	4-Chloro-1-napthol (4C1N)	Insoluble	Immunoblotting
	3-(*p*-hydroxyphenyl)propionic acid (HPPA)	Soluble	Immunofluorescence
Alkaline phosphatase	*p*-Nitrophenyl phosphate (*p*NPP)	Soluble	ELISA
	5-Bromo-4-chloro-3-indolyl phosphate (BCIP)/nitro blue tetrazolium (NBT)	Insoluble	Immunoblotting
	Fast red/naphthol AS-TR	Insoluble	Immunoblotting
	4-Methylumbelliferyl phosphate (4-MUP)	Soluble	Immunofluorescence
β-Galactosidase	*o*-Nitrophenylgalactoside	Soluble	ELISA
	4-Methylumbelliferyl galactopyranoside	Soluble	Immunofluorescence
Urease	Urea + bromophenol purple or phenol red pH indicator	Soluble	ELISA

surement. In addition, some commercial immunoassay systems are fully automated and include bar code specimen ID, automated reagent additions, measurement of result, and printout or data output to a computer. For foodborne microbial antigens, the VIDAS system (bioMerieux), Opus (Tecra), and EIAFoss (Foss Electric) are examples of automated immunoassays.

63.5 EXAMPLES OF IMMUNOASSAYS

63.5.1 Agglutination

Agglutination reactions require solid particles, in this case the whole target bacteria. Colonies are mixed into saline on a glass slide to produce a smooth suspension. Specific antiserum is added (usually hyperimmune rabbit or goat serum), and the slide is rotated gently to provide very slow mixing, allowing antigen and antibody to join. Because IgG molecules are divalent and IgM molecules are pentavalent, an antibody may attach to two or more antigens (organisms), allowing the rapid development of large, lattice-type structures (Figure 63–2) that are easily visible to the naked eye. Some isolates are prone to autoagglutination; thus a control test is necessary, in which the organism is mixed into saline or normal rabbit serum.

Greater levels of sensitivity can be achieved in a tube agglutination where the reaction between antibody and antigen is performed in a larger volume of liquid. The tubes are incubated, generally at 37° C, partially immersed (one third) in a water bath to give gentle mixing by convection currents. Incubation times range from 1 to 24 hours; results generally are read by eye but can be measured using a spectrophotometer (reduction in absorbance due to agglutination) or a nephelometer (reduction in light scattering due to agglutination). Alternatively, a microwell plate method may be used,[99] particularly for testing of isolates against a large number of antisera. This provides good control over the technique and economic use of reagents. The results may be read by eye (with optional magnification) or in a microwell plate spectrophotometer. Agglutination tests are used extensively for the identification and serotyping of a wide range of foodborne pathogens. Examples of the use of agglutination test systems for pathogenic bacteria are listed in Table 63–3.

63.5.2 Passive Particle Agglutination

Principle. When specific antibody is coupled to small particles, for example latex particles, it retains antigen-binding activity and the visibility of aggluti-

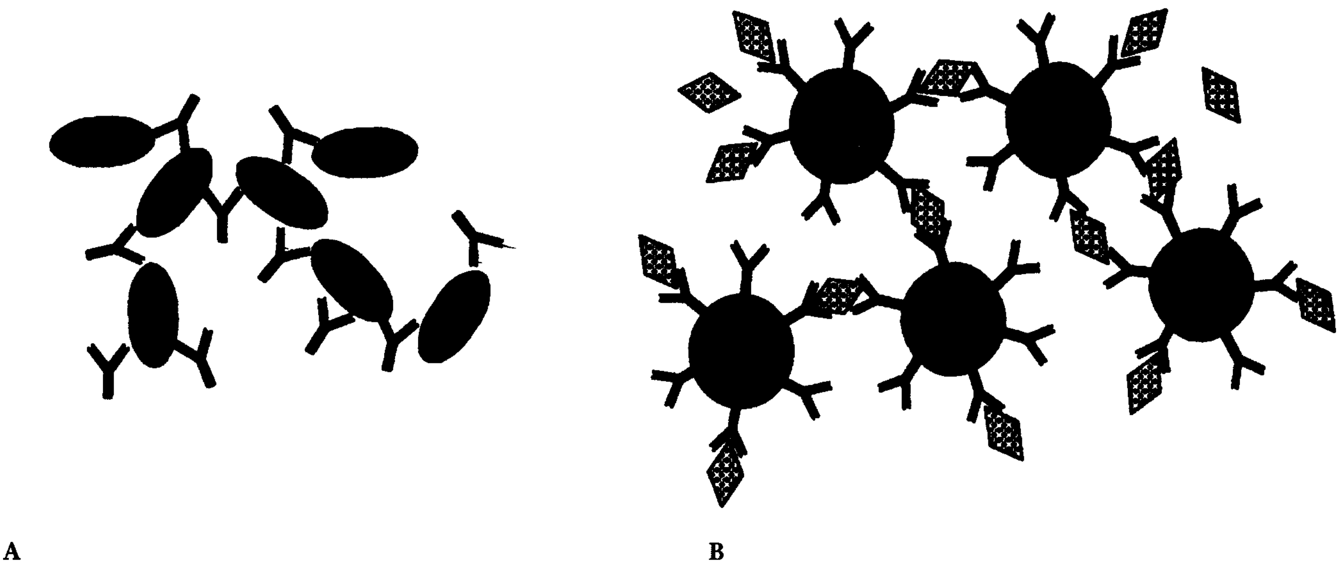

Figure 63–2 Agglutination Reactions. **A**, Agglutination of bacterial cells. Cross-linking by specific divalent IgG molecules causes the formation of clumps. **B**, Passive particle agglutination. Specific IgG on the surface of latex particles is cross-linked by soluble antigen molecules.

nation is enhanced and sensitivity increased. Passive particle tests can be used to detect both soluble and particulate antigens. The principle of passive particle agglutination is illustrated in Figure 63–2. Many types of particle may be used. The chief requirements are:

1. small, uniform, particle size (<1000 nm diam.)
2. suitable color or refractive index to be visible against a contrasting background
3. capable of being coated with protein (sensitization)
4. remaining as discrete particles after sensitization
5. the antibody after sensitization must retain antigen reactive capabilities.

Commonly employed particle types include red blood cells (RBC), latex particles, Staphylococcal Protein A, and colloidal gold.

Red Blood Cells. RBC membranes are particularly suitable after chemical treatment to receive protein sensitization. These cells are treated to fix the cell membrane, making them resistant to lysis and more stable, plus surface modification to accept antibody sensitization. Treatments may be with trypsin or neuraminidase, fixation with formaldehyde, glutaraldehyde, or dimethyl suberimidate, and membrane surface modification with tannic acid.[56] After treatment, antibody is attached to the cells by incubation and any uncoated sites are blocked with a suitable protein solution such as bovine serum albumin or casein. Blocking is necessary to avoid nonspecific binding. RBC agglutination tests have been developed for many organisms, including *Campylobacter*,[76] *Clostridium perfringens*,[36] and *Aeromonas* spp.[40]

Latex Particles. These particles, produced by the emulsion polymerization of organic monomers, have the advantage of high degrees of monodispersity. They are available with a wide range of surface properties, sizes, and colors. For simple passive sensitization, the latex suspension is diluted in a suitable buffer and mixed with antibody solution. Coupling of the antibody is rapid and occurs within 5 to 30 minutes, although final reagent stability may not be achieved for another 24 hours. Washing the particles and blocking of unsensitized sites usually are necessary. Polystyrene particles are most commonly used for passive sensitization. Where difficulties are encountered in attachment of antibody, a covalent method of sensitization may be employed.[48,68,80] Carboxylate-modified particles have surface-bound carboxyl (COOH) groups that may be chemically coupled to amino groups on antibody molecules using water-soluble carbodiimides. Other covalent meth-

ods are available but less frequently used. The very high affinity of biotin for avidin (or streptavidin) may be useful in preparation of latex reagents,[95] because this avoids harsh treatments that can damage antibody. Colored latex particles can provide enhanced visibility due to increased contrast.

A considerable number of latex agglutination tests, both commercial and in-house, have been developed for use in identifying organisms, including *S. aureus*,[32] *Campylobacter jejuni* and *C. coli*,[43] *E. coli* serogroup O157,[61] *E. coli* heat-labile enterotoxin,[34] *C. perfringens* type A enterotoxin,[63] *Vibrio cholerae* O1,[108] *V. parahaemolyticus*,[14] and *Salmonella* spp.[41] Latex agglutination has been used successfully to detect *Trichinella spiralis* antigen in pork samples[16] and for detection of *Penicillium* and *Aspergillus*.[51]

Staphylococcal Protein A (SPA). Protein A is an antibody-binding protein found on the surface of *S. aureus* cells; analogous proteins are found on some other species, notably Protein G on some Lancefield group G Streptoccocci. *Staphylococcus aureus* cells grown to high density, and when fixed, provide a suitable solid phase for the attachment via the Fc end of IgG. Coagglutination is the usual term for agglutination tests employing SPA. Relatively few immunological tests have used SPA but they have the advantage of correct orientation of IgG molecules after coupling. A coagglutination test for pathogenic *Vibrio* species was developed that used four species-specific monoclonal antibodies for the identification of *V. mimicus*, *V. vulnificus*, and *V. cholerae*.[101] Both the heat-stable and heat-labile antigens of *C. jejuni and C. coli* have been used for serotyping by coagglutination[117] and a commercial kit is available for Lancefield grouping of streptococci.

Passive particle agglutination tests usually are read by eye using glass or disposable card or plastic slides. Whole cells are the usual target but antigen extracts may be used. The sensitivity of such tests rarely exceeds 10^7 colony forming units (cfu) per ml, but this is not usually a problem when testing colonies or cultures and the tests are simple, rapid, and relatively inexpensive. Better sensitivity has been achieved in the detection of soluble antigen.[51]

Passive Particle Tube Agglutination Tests. Tube tests have been developed using RBC (hemagglutination), gold sol, and latex particles. These assays use the differences in the settling pattern of antibody-coated particles when they are exposed to antigen. Salomon and Tew in 1968[91] developed a test for the detection of *Staphylococcus* enterotoxin B in which the sample is mixed with antibody-sensitized latex particles and incubated overnight. Agglutination is detected by observation of the sediment pattern. This type of agglutination test uses microtiter plates and antibody-coated latex particles for the detection of microbial toxins either in food or from liquid broth cultures of food isolates. These reversed passive latex agglutination (RPLA) tests have the advantage of relatively high sensitivity but with visual reading of the results. When agglutination occurs, the large clumps settle to the base of the well but friction resistance stops the clumps from rolling down to the base of the V-shaped well. Where no agglutination occurs, the discrete particles, as they settle out, roll down to the bottom of the V-well. Measurement of the amount of toxin is achieved by adding the latex suspension to a series of dilutions of the sample. The highest dilution giving a positive result is used to calculate the toxin level in the sample. RPLA tests have been developed for Staphylococcal enterotoxins,[87,98] *C. perfringens* enterotoxin,[1] *V. cholerae* and *E. coli* heat-labile enterotoxin,[92,105] *Bacillus cereus* diarrheal enterotoxin,[4,5,11,25] and *E. coli* verocytotoxins 1 and 2. The incubation time for RPLA tests is 20 to 24 hours; however, a microtiter plate centrifugation technique can cut the time to just 4 hours.[3]

63.5.3 Precipitation Reactions

Liquid Phase Reactions. Where a reaction develops between soluble antigen possessing multiple antigenic determinants and specific soluble antibody, cross linking and lattice formation occur. The ratio of antigen to antibody molecules is much more critical than in agglutination and an excess of either may result in a failure to develop sufficiently large complexes to become insoluble and therefore visible. Tube precipitation tests are, therefore, uncommon and performing precipitation tests within a gel matrix is more usual.

To prevent antigen or antibody saturation, a series of dilutions should be made of both antigen and antibody solutions in 0.01M, pH 7.4, phosphate buffered saline. Each dilution of antiserum is mixed with each dilution of antigen to form a checkerboard pattern. Incubation is at 37° C for 24 hours or longer (the minimum detectable levels improve with further incubation). The dilution steps should be close together (eg, neat, 1/2, 1/4, 1/8) to avoid missing critical equivalence points. Precipitation may be improved by the addition of 3% polyethylene glycol (PEG) of MW 6000. The identification of Lancefield group D antigens in enterococci by tube precipitation has now largely been superseded by latex agglutination.

Immunodiffusion Reactions. Diffusion within a gel allows gradations of the concentration of either or both of the ligands. As the antigen and antibody diffuse toward each other, areas of optimum antigen/antibody ratio develop and visible precipitation occurs at appropriate concentrations. Agarose gels are most frequently used as the matrix. Agarose is a purified derivative of agar, and aqueous agarose gels are economical, easily prepared, and allow the free movement of antigens and antibodies, including the larger molecules such as IgM. Agarose gels also are nontoxic, therefore allowing excised precipitin bands to be used for animal inoculation. Agarose usually is prepared at 1% (w/v) for general immunodiffusion work. Lower concentrations can lead to weaker gels that are difficult to work with, and higher concentrations can inhibit molecular mobility and increase the reaction time. The composition of the liquid phase used to prepare the gel is not too critical; however, salts are required to maintain ionic strength and the pH should be within normal values for antigen/antibody reactions. Therefore, suitable solutions include phosphate buffered saline (PBS) and barbitone buffer. The addition of 3% PEG will improve precipitin bands. With increasing temperature, diffusion speed increases but the resolution of precipitin bands diminishes. Most immunodiffusion assays are therefore conducted at 4° C; this also reduces the opportunity for microbial contamination to affect results. A preservative such as 0.1%

sodium azide may be added. Two immunodiffusion techniques are in common use:

- **Gel Double Diffusion (GDD).** This is useful for detecting specific reactions between antibody and antigen and for showing whether apparently identical reactions are related. The usual pattern is a central well surrounded by six equidistant wells. This central well contains either an antiserum or an antigen preparation with the peripheral wells containing the opposite analyte. The antigen/antibody ratio is very important, and several dilutions of both antisera and antigens should be prepared. Once the antiserum dilution has been optimized, future work using this dilution may require only minimal variants of antigen concentration. The line patterns show whether the antiserum in adjacent wells shares complete, partial, or no homology (Figure 63–3). When lines cross, there is no shared identity; when there is a complete joining with a rounded corner, there is complete identity and the detected epitope is reactive with the same antibody in both wells. If the same complete identity pattern occurs but with an additional spur, this is interpreted to indicate an antigen-reactive antibody in addition to that found in the adjacent well.
- **Radial immunodiffusion (RID).** In RID, the antiserum (about 0.5%) is added to the agarose while still molten but cool enough to avoid antibody damage (ideally below 50° C). When set, wells are cut in the gel and the antigen preparations added. The antigen diffuses into the gel containing constant antibody concentration. As it diffuses, precipitation and therefore immobilization occur. Unreacted antigen continues to diffuse until it complexes. The size of the precipitin ring is therefore dependent on the concentration of antigen. RID is often used to measure the amount of antigen present in a sample by constructing a standard curve using known concentrations of standard antigen. It is also possible to add antigen to the agarose with serum in the well for the measurement of antibody concentration. This is known as reverse RID (RRID) and may be used, for example, in comparison of batches of antiserum.

Perhaps the major use in food microbiology for agarose diffusion methods has been the identification of Staphylococcal enterotoxins (SET). A culture filtrate of the *S. aureus* isolate is placed in the central well and antiserum reactive with the major SET types A, B, C, D, E, and possibly others are placed in the peripheral wells. With subtype-specific antisera, further identification is possible. Modifications, such as the microslide gel double diffusion test,[12] and techniques to improve the analysis of larger numbers of isolates have been introduced.[64,104]

63.5.4 Immunofluorescence

The use of antibodies labeled with fluorescent dye was introduced by Coons in 1941.[18] The fluorescent antibody (FA) technique has been applied to the rapid detection of salmonellae in centrifuged samples of enrichment broth and also by a modified method of plating the enrichment culture onto brilliant green agar for detection by microcolony FA.[110] An indirect immunofluorescence assay was developed to detect five of the major fungal spoilage organisms in tomato purees.[84] The assay reduced errors associated with the Howard mold counting technique. A fluorescent sandwich immunoassay using a portable fiber optic sensor was developed to detect staphylococcal enterotoxin B in ham and other samples. This allowed onsite analysis of suspect food samples.[109] Fluorescent methods are highly sensitive, but their use is limited due to the natural fluorescence of many materials found in samples and the environment. Techniques to improve the signal-to-noise ratio include the use of fluorophores with a high Stokes shift (the difference between the excitation and emission wavelengths) and time-resolved fluorescence using lanthanide chelate labels such as europium where, as well as the long Stokes shift effect, the fluorescence is longer lived allowing for natural fluorescence to be filtered out by the instrumentation.[35]

63.5.5 Membrane-based Immunodiagnostics

Defined porosity membranes in materials such as nitrocellulose, polycarbonate, polysulphone, and nylon are used commonly in filtration and more recently in immunodiagnostic tests. Protein such as antibody may be bound to the surface of the membrane allowing use in colony-blot and dot-blot tests using enzyme immunoassay reagents. Colony-blot methods have been developed, for example, for heat-labile enterotoxin-producing *E. coli* isolates[94] and *C. botulinum* toxin.[39]

Flow-through devices[114] generally have a capture antibody bound in a defined region to a membrane. The sample is added and allowed to flow through the membrane into absorbent pads on the other side. A

specific antibody-enzyme conjugate is added followed by substrate. A colored result indicates a positive result. Variations of the technique include use of antibody-bound latex particles to provide an increased surface area for antigen capture. These tests are generally qualitative, but by use of a reflectance meter a quantitative result may be obtained.

Lateral-flow devices use the ability of some membrane materials to permit liquid to flow along their length. The term immunochromatography has been applied to assays using this process. Enzyme conjugates or colored latex particles can be used as the indicator of binding. The original latex, lateral flow device[22] consists of a specific antibody (usually monoclonal) bound to the membrane in a thin line at a region along the strip. At the sample application zone, there are colored latex particles sensitized with another specific antibody. These particles are free to move in the capillary flow of liquid within the membrane. When sample liquid is added, the antigen, if present, will bind to the latex particles and will move along the membrane strip in the liquid flow. The antigen will bind, together with its colored latex label, to the immobilized antibody line, giving a defined colored line. A second antibody line further along the strip consists of an antimouse IgG antibody that will bind the monoclonal sensitized latex particles directly and thus will act as a control. This test has been applied to the detection of *Listeria monocytogenes* in enrichment culture.[83] Such lateral flow tests have just two steps, the addition of a sample and reading the result a few minutes later.

63.5.6 Enzyme-Linked Immunosorbent Assay

ELISA tests, also known as EIA tests, use enzymes conjugated chemically to antibody as the tracer. They are generally heterogeneous immunoassays although there are some homogenous assays, the best-known of these being enzyme multiplied immunoassay technique (EMIT). In clinical pathology, some assays are used to detect specific antibodies produced in response to infection. To detect microorganisms or toxins in food or culture, both immunometric and, less frequently, competitive tests are used.

ELISA tests all follow certain basic principles. A typical assay consists of a number of specific binding steps and a number of wash steps to remove unbound material (Figure 63–4).

The most common format for ELISA tests uses 96 microwell plates. Also available are strips of 8 or 12 wells that snap into plastic holders and are useful for conducting fewer tests. A wide variety of instrumentation is available for the microtiter plate format including multiple well pipettors, plate washers, and multiple wavelength spectrophotometric plate readers. Programmable robotic systems can be purchased also to automate much of the work. Macrobeads and microbeads may be used as the solid phase, and a variety of dipstick type formats are also available.

It is necessary to go through a lengthy optimization process to develop ELISA tests, including choice of the solid phase, selection of the capture and conjugate antibody, selection of the conjugate enzyme and substrate system, conjugation method, incubation times and temperatures, washing steps, and reading the result of the reaction.

Enzyme-linked immunoassays offer the opportunity to reduce the assay time required for the detection of many foodborne pathogens that produce a specific antigen suitable for this test. Also, where technical experience is lacking for colony recognition of pathogens on selective agars, its replacement with an ELISA may improve reliability. Numerous reports since 1977[54] on the performance of laboratory prepared and commercially manufactured ELISA methods are available in the literature. Enzyme-linked immunoassays have been described for most of the major foodborne pathogens. Because of their sensitivity, enzyme-linked immunoassays are ideal for the detection of bacterial toxins. Examples are the demonstration of *B. cereus* diarrheal toxin,[25] *C. perfringens* enterotoxin A,[113] the heat-labile enterotoxin,[89] and heat-stable enterotoxin[86] of *E. coli* and *S. aureus* enterotoxins.[70]

Many commercially produced ELISA kits are now available for the detection of foodborne pathogens and toxins. While the performance of many of these kits has been compared with recommended or standard methods, comparisons between kits for detect-

ing the same microorganism or toxin are limited.[31] The minimum number of bacteria that can be detected in a standard sandwich ELISA is generally $\sim 10^5$ cfu ml^{-1}. Culture in selective enrichment broth (with pre-enrichment where advocated) usually is necessary to give such numbers, but the selective conditions may result in poor expression of the target epitope. Subculture into another, often nonselective, medium is then necessary to stimulate antigen expression and reduce any interference from food. If the target antigen is hidden or particulate (eg, a cell-wall component or flagellum), treatment to render it in a reactive (soluble) form is necessary. Such treatment often multiplies the number of target molecules significantly by depolymerization giving increased test sensitivity. Automation of the assay[55,72] and methods to reduce the period of culture are being sought continuously to achieve a total test time of <24 hours.

In the analysis of foods or a culture supernatant, for the presence of a toxin several factors contribute to the quality and thus the assurance of the assay. Amplification of ELISA tests can improve their sensitivity. In the most well-known example, an alkaline phosphatase antibody conjugate is used for the dephosphorylation of nicotinamide adenine dinucleotide phosphate (NADP) to nicotinamide adenine dinucleotide (NAD). Alcohol dehydrogenase reduces the NAD to NADH and diaphorase converts it back to NAD with the simultaneous reduction of p-iodonitrotetrazolium violet to a purple formazan dye. The continuous cycling of the NAD reaction causes the formation of hundreds of formazan molecules. A similar amplification technique was used to increase the sensitivity of an assay for the *Clostridium botulinum* neurotoxin from food,[100] allowing it to be used as a replacement of the mouse bioassay. Another amplification technique, also for *C. botulinum* neurotoxin, used ELISA-ELCA, an ELISA-enzyme-linked-coagulation-assay.[28,29,85]

63.5.7 Enrichment Serology and Motility Enrichment

A number of researchers have developed methods for the rapid detection of salmonellae using a combination of pre-enrichment, enrichment, and immunological stages.[9,106] The common factors in most of the methods are the selective growth of presumptive salmonellae in a highly motile form (motility enrichment) and the detection by *Salmonella* polyvalent H sera or reagents prepared from such antisera. Various serological tests have been used including standard ELISAs, fluorescent antibody, filter-membrane based ELISA,[54] and latex agglutination.[45] A collaborative study on the use of modified semisolid Rappaport-Vassiliadis (MSRV) medium and serological detection of *Salmonella* from foods was performed by De Zutter et al.[27] Several commercial products are now available that are based on the enrichment serology principle.[21,44] The enrichment serology technique has been extended to include other foodborne pathogens of major concern, such as *Listeria* by ELISA[62] and *Campylobacter* by latex agglutination.[81]

63.6 THE USE OF IMMUNOMAGNETIC SEPARATION (IMS) TECHNIQUES IN FOOD MICROBIOLOGY

Superparamagnetic iron oxide Fe_3O_4 particles can move within a magnetic field (yet lose their magnetism when the field is removed); thus when a magnet is placed at the side of a tube containing a liquid medium, suspended particles will rapidly move to that area. Antibody is attached to either ferric oxide particles or ferric oxide incorporated within a polymeric shell (paramagnetic latex particles) to provide an antigen capture reagent. The use of such particles is a very effective means of separation and concentration. Washing steps, to remove food material and contaminating antigens, are also very easily performed. Antigen may be eluted from the particles, usually by reduced pH treatment. The concentrated and purified eluted antigen can be detected by a conventional immunoassay or alternatively the antigen-coated particles may be used in an immunoassay without elution. Stannard et al.[107] developed a magnetic enzyme immunoassay (MEIA) for Staphylococcal enterotoxin B. This used polyacrylamide agarose beads containing entrapped iron oxide particles. Enterotoxin captured from processed food samples on the particles was detected by an antibody-coupled peroxidase.

Antibody-sensitized paramagnetic particles have been proposed for the capture of live bacteria from food samples.[37] To a sample of food, specific antibody-(usually antisomatic or antiflagella antibody) coated paramagnetic particles are added. An incubation step allows binding of the target organisms to the particles. After separation and wash steps, the now concentrated and cleaned suspension is pipetted onto agar culture media, streaked-out, and allowed to grow normally. Alternatively, samples are pre-enriched in buffered peptone water prior to IMS of target organisms; this is followed by selective enrichment before plating onto selective media. Or the particle-bound organisms are placed into pre-enrichment, then enrichment, culture prior to solid media culture. The separation of target organisms from most of the rest of the sample results in a reduction of competing microflora. This therefore can aid recovery of the target organisms particularly when they are sublethally injured. IMS has been used for capture of live salmonellae,[19,60,82,102,115] *V. parahaemolyticus*,[112] *Listeria* spp.,[2,30,65,103] *S. aureus*,[49] and *E. coli* O157.[6]

IMS can be combined with other technologies such as the polymerase chain reaction (PCR) for *Yersinia enterocolitica* O3,[52] Salmonellae,[116] *E. coli* O157,[47] and *Coxiella burnetii* in cows.[67] A technique has been developed for the detection of hepatitis A virus (HAV) in American oyster, in which human anti-HAV antibody coupled to magnetic beads is used to capture HAV from extracts for subsequent analysis by PCR.[58] Yu and Bruno[119] used an immunomagnetic-electrochemiluminescent system for the detection of *E. coli* O157 and *Salmonella typhimurium* in food samples with a stated sensitivity rate of 10^3 CFU ml^{-1}. Immunomagnetic separation has been used to aid the flagella phase inversion that is necessary for the H-serotyping of salmonellae.[23] The detection of type A enterotoxin of *C. perfringens* in food extracts has also been achieved using IMS.[20]

IMS is a powerful technique that has been shown in most studies to radically increase both the sensitivity and specificity of organism detection and can reduce analysis time. For the detection of *Listeria* from environmental samples Mitchell et al[65] found that the use of immunomagnetic beads detected *Listeria* in 100% of samples at contamination levels where a standard cultural method gave detection in only 36% of samples. Also, quantitative results were produced within 24 hours for both positive and negative samples as no enrichment was required, while for the standard cultural method qualitative results required 6 days for positives and 3 days for negatives. In contrast, Poppe et al.[78] found only a little improvement in isolation of *Salmonella* from raw poultry samples. When optimized, the IMS technique yielded 65% positives compared with 60% by conventional methods. Mansfield and Forsythe[59] found in a comparison of an IMS method and a conventional enrichment method for the detection of salmonellae in herbs and spices that of 468 samples analyzed, 195 (41.7%) were positive by both methods. Eighteen were positive only by IMS enrichment and 19 only by the conventional method and not IMS. As with other immunodiagnostic tests, IMS requires high-specificity antisera for the efficient separation of target bacteria from background contamination. In a study[17] to compare conventional culture with IMS methods for the detection of *Salmonella* in sausages it was found that although IMS improved the detection by almost two-fold, there was a high level of false positives due to *Citrobacter freundii*, some serotypes of which share common antigens with *Salmonella*.

A high rate of nonspecific binding (NSB) by immunomagnetic beads has been observed also in some studies. The use of wash steps employing specific additives has been found useful to eliminate NSB. Tween 20 (0.002% to 0.005%) has been used to aid the IMS of *E. coli* O157 from beef mince[118] and Tween 20 (0.1%) plus 4% skim milk for *Salmonella livingstone*.[115] The skim milk was found to be effective at blocking NSB due to *Aeromonas hydrophila*. Reviews of magnetic separation methods have been given by Olsvik et al.[73] and specifically for food by Safarik et al.[90]

63.7 STANDARDS

The use of controls or standards is very important in immunoassays. Their use shows that each reaction step and each washing step of the assay has been conducted correctly. The minimum requirements for controls are a known high-level calibrator antigen, a known low-level calibrator antigen, and the sample diluent (= negative control). Additional controls could include further known antigen levels to provide a standard curve, appropriate food sample to exclude false positive results, and real or artificially inoculated food or culture preparations.

63.8 FACTORS AFFECTING IMMUNOLOGICAL TECHNIQUES

Strain Variation. Due to the heterogenous nature of microorganisms, variations in antigen production will occur between strains. In plate cultures of *E. coli* capsular serotype K1, two types of colony were found with different reactivity toward K1 antiserum. One form ($K1^+$) gave strong agglutination, the other ($K1^-$) gave weak agglutination; the $K1^+$ form contains the polyneuraminic capsular polysaccharide in an O-acetylated form.[74] Genotypically motile organisms including salmonella may fail to produce flagella in culture, and motility enrichment is a useful technique to increase the numbers of actively motile bacteria. Some isolates of salmonellas are, however, incapable of producing flagella. The O111 inag-

Next Page

glutination phenomenon is found in live cultures of *E. coli* serogroup O111 where such large quantities of free O-polysaccharide are produced that the antibody is saturated, thus eliminating the agglutination of the whole cells.[38]

Temperature. Immunological reactions, in common with other chemical reactions, are affected by temperature. With increasing temperature, the rate of antigen/antibody collisions increases, leading to increased capture or binding. An opposing force also will occur, because due to the protein nature of antibody, increasing temperature will lead to increasing thermal denaturation. This also occurs with heat-labile antigens. Small, thermally induced changes in the structure of antibody or antigen can cause partial or complete loss of binding and hence reduction in the sensitivity and speed of reaction. Thermal effects also will affect other proteinaceous materials used in immunoassays such as enzyme conjugates; again, increasing temperature causes increasing rate of catalysis but also increases thermal denaturation. Nonprotein materials also may be affected, in particular the substrates used in ELISA tests. Conversion of substrate to colored product is greatly accelerated by contact with enzyme but will take place slowly in the absence of enzyme. An alteration in temperature from that specified by the manufacturer or that validated in a trial will shift the assay sensitivity and specificity and may cause an increase in false positives or false negatives. Many tests are conducted at room temperature for ease of use but this is an ill-defined value and could range from below 10° C to above 30° C depending on location, time, and laboratory facilities. Wherever possible, the immunoassay laboratory should be maintained between 18° C and 22° C. The ambient laboratory temperature at the time the assay is conducted should be logged to aid in tracking discrepant results.

The storage temperature of immunoassay reagents is very important. For the majority of commercial kits using liquid reagents, refrigeration is required. The expiration date on the product is derived from shelf life studies (stability tests). Usually for each 10° C rise in temperature, the effective shelf life of the kit will halve. For some reagents, freezing will preserve their activity beyond the stated expiration date; for others including particle-based assays, especially latex suspensions, freezing, even momentarily, may cause complete and irreversible autoagglutination.

Repeated freeze-thawing of reagents is particularly damaging; a better policy is to freeze in small aliquots, which may be removed from the freezer and used once only. When preparing standards for future use in checking product sensitivity, it should be borne in mind that even freezing will not maintain the effective strength indefinitely. The best way to maintain nonparticulate standards is by freeze drying, to achieve a low moisture level, and then by subsequent storage in a frozen state. When immunoassay reagents are removed from cold storage, it is advisable to bring them to room temperature before use. If this is not done, the rate of reaction will be slower, causing reduced sensitivity and possibly false negative results. This is of particular importance for rapid tests that may reach completion time before attaining the correct temperature.

Growth temperature of microorganisms can affect expression of antigens; for example, the putative flagellin from *L. monocytogenes* is expressed abundantly when grown at 20° C, but only in trace amounts at 37° C.[75]

pH. In general, the optimum pH for antigen-antibody binding steps in an immunoassay is at physiological pH, 7.3 to 7.4; however, antibody binding activity is surprisingly tolerant of pH variations. Denaturation of antibody and antigen will occur at much higher and lower pH values. In a population of polyclonal antibodies, this denaturation pH may be spread over a wider range; for monoclonals a tighter cut-off is to be expected. Some food samples may be too acidic for efficient detection by immunoassay of microorganisms or their toxins. Best results are obtained by neutralizing the sample before testing. Extraction or dilution in buffer should effectively neutralize acidic food samples.

Time. Almost all immunoassays rely on timed steps. Deviation from these times will cause changes in the sensitivity/specificity balance. With ELISA tests, if the incubation times are reduced, lower binding will occur. Latex agglutination tests always have a cut-off time, usually 1, 2, or 3 minutes. The sensitivity is set by the manufacturers to provide at the limit time a division between positive and negative results. If the slide is not rocked for sufficient time, weak positives may be missed. Results after the limit time should be ignored as nonspecificity will increase with time. Although immunochromatographic tests have a built-in control line, the tests require further incubation up to the manufacturer's limit time to detect weak positives because even after the control line has formed, there is a continued flow of liquid along the device.

Extraction Efficiency. Microorganisms in food may be hidden effectively from detection due to their being deeply embedded within the matrix. A key factor in detection of microorganisms and their products in food is an efficient means of separating the target from the matrix. Methods of food extraction can be found in Chapter 61. The availability of antigens may be increased by specific heat and/or chemical treatments. For example, heating *S. typhimurium* at 100° C in 50mM ethylenediaminetetraacetate (EDTA) was found to dissociate its antigens into a form that resisted sedimentation at normal centrifuge speeds and caused a marked increase in the rate of immunoreaction and sensitivity in an enzyme immunoassay.[8]

Ionic Strength. The antigen-antibody reaction involves weak, physical, noncovalent bonds, and the primary and specific reactions involve coulombic and Lifshitz van der Waals forces. The coulombic bonds in particular are sensitive to both changes in ionic strength and pH.[24] Optimum ionic strength lies generally around that of physiological solutions.

Viscosity. The reaction between antigen and antibody only occurs when the reactants are in very close proximity. The rate of reaction is dependent on the number of specific bindings. With a high viscosity medium, convection currents and Brownian motion will be reduced, and the number of reactions will be reduced, causing a lower rate of reaction and therefore lower sensitivity. Agglutination reactions in particular are severely affected because they depend on the coming together of relatively large particles to form larger agglomerates. The movement of these particles through a viscous medium is impeded and, as agglutinate size increases, the movement reduces further.

Cross Reactions. Cross reactions are caused by unwanted but true antigen/antibody reactions that cause false positive results. There are two basic types of cross reaction.

- **Type 1**. The specific antibody reacts not only with the target organism but with an identical epitope present on another organism or present in the food substance or culture medium. Attempts to remove this cross reaction by absorbing the antiserum with the nonspecific organism will result in reduction or elimination of both the nonspecific and the specific reaction. Other polyclonal serum batches or modifications in the vaccine preparation may produce better specificity. It is therefore the aim of most monoclonal development programs to prepare antibodies with reactivity toward unique epitopes.
- **Type 2**. A polyclonal antiserum having antibody that reacts with the specific target epitope may also possess antibody reactive with minor antigens on the target organism. These minor antigens may be present on other organisms (as minor or major antigens) or as elements of the food or culture medium and, therefore, the antibody will react with them. Absorption of the serum with the cross-reactive organism usually will result in improved specificity without loss of the specific antibody. There is a known cross reaction between Staphylococcal enterotoxins A and E.[7] There are cross reactions between *E. coli* O157 antisera and the *Salmonella* O30 serotype.[97] Some strains of *Escherichia hermannii* are found to cross react with *E. coli* O157 antiserum.[10] This is related to the common occurrence of an N-acyl derivative of 4-amino-4,6-dideoxy-D-mannopyranosyl residues in the O-polysaccharide fractions of the LPS of the respective organisms.[77]

Nonspecific Binding. Nonspecific binding is caused by one component of an assay binding to another, but the term excludes a specific reaction between antigen and antibody. In latex agglutination tests, blocking unused sites on the latex particles after sensitization of antibody is necessary. If unblocked sites remain, protein may bind nonspecifically and cause cross-linking, resulting in false-positive agglutination. In ELISA tests, the NSB of the antibody-enzyme conjugate to the solid phase would cause a false positive signal. Even with perfectly blocked solid phases, a degree of NSB may occur and cause the assay to be less specific than desired. This is a severely limiting factor in homogenous assays as interfering substances, if present, are not removed from the assay. In heterogenous assays, the washing steps can remove most potential interfering substances. The inclusion of a detergent, usually Tween 20, can increase the effectiveness of washing and thus aid specificity. The improvement in specificity will also allow for tests to give better sensitivity.

Washes. If there are wash steps in an assay, the manner in which they are conducted can affect the assay sensitivity, specificity, and precision. For some assays, particularly those detecting large macromolecules, overvigorous washing can detach antigen and result in reduced sensitivity. Conversely, inadequate washing can result in increased NSB and therefore reduced specificity.[93]

Dilution. The amount of sample dilution will affect the assay sensitivity. Dilution may be required to mitigate the effects of sample interference. Concentration of the sample may be used to increase sensitivity.

Chemical Interference. Samples that contain substances such as lipids, detergents, or acids may reduce the sensitivity or specificity of assays. Sample purification may be required to reduce the effect of such substances. Lysozyme causes nonspecific results by cross linking IgG molecules.[33] This lysozyme interference may be overcome by the use of Cu^{2+} ions and ovalbumin.[71]

Protein A and Protein A Like Substances. Protein A present in the cell walls of *S. aureus* will bind the Fc end of IgG,[66] and its presence as a contaminant in a sample may cause interference in an immunoassay. Nonspecific agglutination of antibody-coated latex particles is a notable example. The use of Fab fragments as an alternative to whole IgG will remove this problem. Some Lancefield group G streptococci possess a similar Fc-binding substance known as protein G. The cyclic adenosine monophosphate (CAMP) factor of *Streptococcus agalactiae* binds to IgG and IgM.[50]

Hook Effect. An excess of antigen in a sample can cause a reduction in reactivity in some assays, particularly those based on particle agglutination and precipitation. This is known as the hook effect, named after the shape of the dose-response curve; it is also called the prozone phenomenon. Antigen excess causes saturation of the antigen-binding sites on the antibody, thus limiting cross-linking of particles and reducing the signal. For those assays that may be subject to this effect, either the sample will need to be prediluted or a number of dilutions should be prepared and tested.

Cross-Well Contamination. The microplate format having wells within very close proximity can suffer from cross-well contamination. A small volume of concentrated sample could cause false positives in adjacent wells. It is therefore important to ensure that the sample is added without causing splashes or aerosol formation. Urease conjugates have been used occasionally in enzyme immunoassays with a urea substrate and pH indicator for signal detection. Possible false positives may be caused due to ammonia liberation affecting the pH of adjacent wells.[57]

Product Drift-Stability. Reputable diagnostic kit manufacturers go to great lengths to establish the effective shelf life of their products, including studies simulating transportation conditions. It is therefore important that products are only used within their stated expiration date. It is likely that in-house produced assays are not so rigorously tested for stability and their sensitivity and specificity are likely to change with time.

Antigen Adherence. Antigens may adsorb onto the surface of glass and plastic containers and on filter membranes. If a sample contains a very low level of antigen, this adsorption can significantly affect the result and may cause false negatives. It has been found beneficial to preblock containers with solutions such as 1% bovine serum albumin.

ELISA Plate Readers. Microplate readers, often assumed to offer precision and accuracy, have been found to produce erroneous results, particularly in well-to-well bias.[42] Therefore it is important to determine the precision, accuracy, and well-location bias in a microplate reader. Regular servicing and calibration are required.

Food As a Sample. Food is a highly diverse material and the complex mixtures of proteins, carbohydrates, fats, preservatives, and other additives in foods may cause a number of effects on immunodiagnostic tests. When testing the sensitivity of an assay on a new food type, it is necessary to inoculate that food with varying known levels of organism or toxin and measure the minimum detection level. This also extends to the use of immunodiagnostic tests on enrichment culture where the foodstuff is still present.

Culture Media As a Sample. Culture media are much less complex than foods. Detection of microorganisms in foods usually involves pre-enrichment followed by enrichment and then isolation on solid media. The indirect detection of food-poisoning organisms using immunodiagnostic tests traditionally has been performed on isolates from agar media; however, many assays have been designed for detection of the organisms in the enrichment medium. Toxin tests may be performed on filtrates of broth cultures or organisms isolated on solid media. Culture media recommended by manufacturers of a kit should be adhered to because cross reactions, although rare, can occur. Also, in the wrong medium, insufficient growth, antigen yield, or toxin production may occur resulting in false-negative results.

Selective media, in particular, can sufficiently alter the organism's growth pattern to produce unreliable results. In such cases, subculture to nonselective media is recommended.

On solid culture media testing, a number of isolated colonies to avoid selection of an unrepresentative type is advisable. The identity of an isolate giving a positive immunoassay result should be confirmed by other means (eg, Gram stain, biochemical reactions) to reduce the possibility of a false-positive reading.

63.9 CONCLUDING REMARKS

In this chapter, the authors have given a brief review of immunological techniques and their application to food microbiology. A limited number of examples have been given that have hopefully demonstrated the advantages of speed, sensitivity, and specificity of immunoassays but also have shown the possible pitfalls and limitations of these tests. The applicability of immunological techniques to each stage of microbiological food analysis (eg, direct detection, culture detection, culture identification) is likely to increase over the coming years. Also, the use of the antigen-antibody reaction for capture of organisms from food before detection by other means such as culture and PCR shows a very promising future. As the requirement for efficient and rapid food analysis increases, validated immunological techniques will be likely to continue to form an important element of routine microbiological analyses.

64.1 INTRODUCTION

Detection of disease-causing microbes in foods has always been a challenging undertaking. The United States (US) Centers for Disease Control and Prevention report the etiologic agent was confirmed in only 38% of the recognized outbreaks of foodborne disease in the US from 1983 through 1987.[18] Because pathogenic microbes may be present at very low levels, they can be difficult to detect in foods amid the indigenous microflora, and components of the foods may also interfere with their detection. Rapid techniques for the detection, identifi-

cation, and enumeration of microbial pathogens present in foods are needed.

Standard methods for recovering bacteria from foods may include enrichment culture followed by streaking onto selective and or differential agar medium or direct plating onto these media. Individual colonies are identified by morphological characteristics. Confirming biochemical and/or immunological reactions and specific tests for microbial virulence factors usually requires between 2 and 5 days.

The invention of the gene probe and polymerase chain reaction (PCR)-based techniques permits the design and development of tests to rapidly detect and identify specific bacterial strains and/or virulence genes without the need to establish pure cultures. These methods have also lessened the need for virulence testing based on bioassays using animals. However, the implementation of these molecular biological techniques (usually designed for use in the research laboratory) to the routine analysis of foods is a formidable task and at present is a major area of activity.

Gene probe tests are based on the concept that single-stranded DNA molecules of complementary sequence will, under the appropriate conditions, reform the double helix. Therefore, if a piece of DNA is appropriately labeled, it may be used to detect complementary genes in the DNA of unknown organisms. If the labeled DNA probe becomes part of a double-stranded structure, it is concluded that the sample contained an organism with a particular genetic capability. There are several assay formats, and sensitivity is usually in the range of 10^4 to 10^6 copies of the target gene. Work on the genetic basis of pathogenicity of foodborne bacteria resulted in the development of gene probes targeted not only to specific genera and species but also toward particular strains that cause disease. Several reviews describe the use of gene probes in general[187,203,230] and their use to detect foodborne bacteria.[141,147,150,370,382]

The PCR is a procedure for the in vitro amplification of specific segments of DNA.[251,301,302] A millionfold increase of the target region usually can be achieved to permit the very sensitive detection (and possibly the quantitation) of specific genes. Introduced in 1985, this technology has been applied in a broad range of disciplines ranging from anthropology to forensics and zoology. The use of PCR to detect foodborne pathogens has been reviewed.[148,179]

Many of the difficulties in using gene probes and PCR-based methods for the analysis of food samples are in the area of sample preparation; that is, releasing DNA from colonies and from food matrices and the removal of inhibitors of DNA amplification.

Progress in the sequencing of nucleic acids and the wide range of potential uses for gene probes helped stimulate the development of methods to synthesize oligonucleotides. PCR-based tests would be laborious to develop and difficult to perform were it not for the general availability of defined-sequence oligonucleotides. In addition, many of the genetic analyses of bacterial virulence factors created a solid foundation for the use of gene probes and PCR applications in that the nucleotide sequences of a variety of virulence genes and taxonomic markers were determined. Conveniently, oligonucleotides used as probes often could serve as primers. The PCR offers a new level of sensitivity and speed for the detection and identification of microorganisms, but the use of gene probes following direct plating or enrichment culture can yield more reliable quantitative estimates of viable pathogens in food samples.

The focus of this chapter is gene probe and PCR-based methods of testing foods for the presence of hazardous microorganisms and not on the use of probes and PCR as research tools. The chapter will outline general mechanisms and formats and give examples of specific applications for foodborne microbial pathogens. Genome characterization methods such as pulsed-field gel electrophoresis (PFGE) and ribotyping, which are becoming more important for the subtyping of strains for epidemiological purposes, will also be described.

64.2 GENE PROBES

Gene probes are labeled DNA fragments and are used for the detection of particular genes by hybridization. The gene probes are labeled so that one may determine whether they have formed hybrids with the sample DNA.

64.2.1 DNA Hybridization

The DNA molecule usually exists as a double-stranded helix held together by hydrogen bonds between adenine and thymine and between guanine and cytosine. The strands can be separated (denatured) by increasing the pH or the temperature. When the pH or the temperature is lowered, the strands will reform the double helix if strands contain similar sequences. If the strands reforming the double helix originate from different sources, the resulting molecules are called hybrids and the process is termed hybridization. When a gene probe is found stably associated with the target DNA, it is concluded that the target DNA contains the same information as that encoded in the probe.

64.2.2 Hybridization Conditions

A major factor in controlling the specificity of hybridization is the temperature at which it is performed. When the temperature is too low, the gene probe will reform the double helix with regions that are not exactly complementary (low stringency), causing false positive results. At too high a temperature, even perfectly matched hybrids will have difficulty remaining in the double-stranded state, and false negative reactions may be observed. Normally, a suitable hybridization temperature is determined empirically but there are a number of algorithms for estimating this temperature. Salt concentration also plays an important role: generally, increasing the salt concentration reduces the stringency; an increased temperature will be required to maintain the stringency.

The concentrations of the gene probe and the target nucleic acid affect the time required for hybridization. At higher concentrations, the reaction will proceed more quickly but when concentrations are too high, self-annealing of the probe or of the target will decrease reaction sensitivity. However, when oligonucleotide probes are used, all the molecules are identical and hybridization of probe molecules with themselves is not a problem. Generally, reactions using synthetic oligonucleotide probes can proceed more rapidly than reactions using long gene probes because higher concentrations can be used and the small oligonucleotides have a faster rate of diffusion.

64.2.3 Hybridization Formats

Several hybridization formats are available. The minimum requirements are that the target DNA is exposed, denatured, and able to be hybridized and that the hybridized probe:target complexes can be identified.

A solid support can be used to anchor either the target DNA or a probe and provide an easy means to remove nonhybridized components prior to detection. A common format, colony hybridization (Figure 64–1), involves the transfer of colonies from an agar plate medium to a membrane. Cells are lysed and the DNA released, denatured, and affixed to the membrane. The gene probe hybridizes with the immobilized target DNA and the unreacted, labeled probe molecules are removed by rinsing. The presence of probe is detected by a method appropriate for the particular probe label. Colonies that contained the target DNA will be indicated by corresponding dots on the membrane. Nitrocellulose filters were first used with ^{32}P-labeled probes and required baking to fix the DNA to the surface.[134] Then Whatman 541 filters were introduced, on which the DNA can be adhered by air drying; these filters also had the advantage of not becoming brittle.[229] Positively charged nylon membranes are reported to be optimal with nonisotopic probes because the nonspecific background signal is reduced.[72] The DNA can be fixed to these filters by either baking or ultraviolet (UV) crosslinking. The transferred colonies often are lysed and the DNA denatured by exposure to alkali solution[134,229] or by the use of microwaves.[74] Cell lysis may also be accomplished by using proteinase K[311] or sodium dodecyl sulfate (SDS).[297] Excess colony debris can be removed mechanically from the membrane surface by gently rubbing it with a tissue soaked in 5-fold concentrated standard saline citrate (5XSSC) solution to reduce background signal especially with digoxigenin-labeled probes.[145]

Colony hybridization may not be sufficiently sensitive for detection of pathogenic microorganisms in foods; for example (1) if the level of the pathogen is too low to be detected by direct plating, (2) when high levels of indigenous microflora are present (usually above 10^6 to 10^7 cells g^{-1}), or (3) if the target genes are on plasmids, which may be lost during enrichment.[149,185,395] Other methods using target DNA immobilized on a solid support are dot blots of lysed and denatured cells from a liquid suspension or amplified PCR product. In a Southern blot format, specific DNA fragments are separated by gel electrophoresis, denatured, and fixed onto a membrane.[322]

In some formats, one gene probe is fixed to a solid surface, such as a dipstick or the bottom of a microtiter dish, and used to "capture" the denatured target DNA. The Gene-Trak® products for *Listeria* or *Salmonella* use a dipstick coated with a "capture" probe targeted to specific regions of the 16S rRNA gene from a lysed cell suspension (Figure 64–2). Because the target is present in multiple copies per cell, the sensitivity of the test is greater than those depending on a single target copy. This increased sensitivity allowed the development of a colorimetric detection system of sensitivity equivalent to the

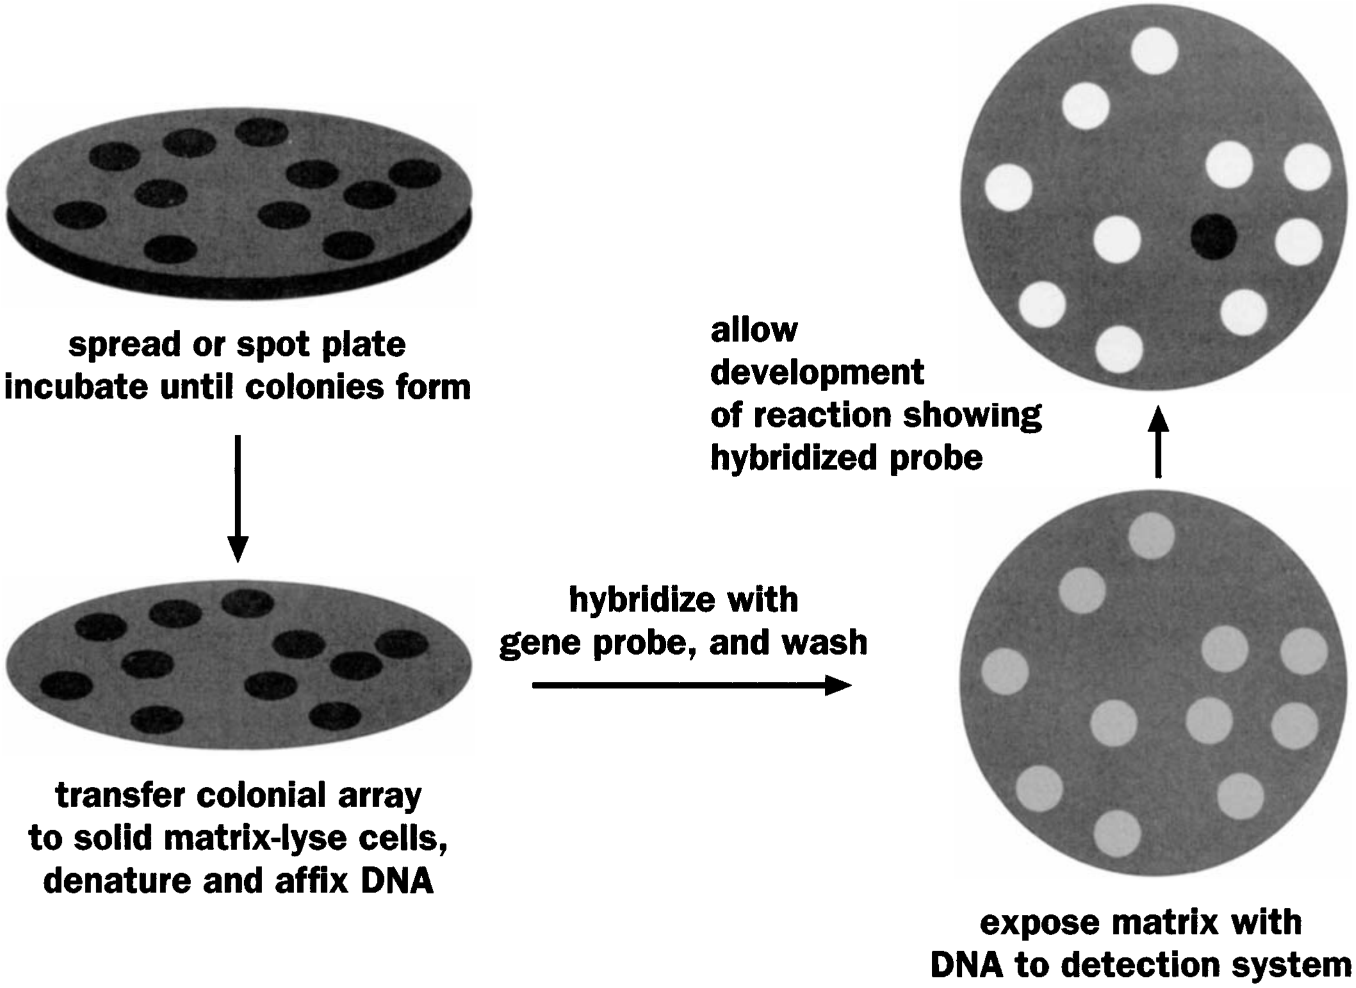

Figure 64–1 DNA Colony Hybridization

isotopic assay. A second probe, a reporter probe, labeled with fluorescein isothiocyanate (FITC) hybridizes with the captured target DNA and is detected by chromogenic methods.[69,192,194]

Hybridization formats also have been developed where all components are in solution. One such system uses two gene probes (each with a unique label) that must be physically close to each other to emit a signal. These two labels will be in proper geometric relationship only when they are bound to the target DNA. Thus, hybridization reactions can be followed in real time with no interference from unbound probes.[53] Another format, available as a commercial kit (AccuProbe *Listeria monocytogenes*) uses a DNA probe complementary to the rRNA of the target organism. The rRNA is released from cells so that it can form a stable DNA:RNA hybrid with an acridinium ester-labeled DNA probe. The unhybridized probes are selectively inactivated by differential hydrolysis. The addition of an alkaline H_2O_2 solution allows the detection and quantitation of light emission from the acridinium esters protected by linkage to the DNA:RNA hybrid.[257]

64.2.4 Labeling of Gene Probes

During the early development of gene probes, radioactive labels, usually ^{32}P, were used to achieve the necessary sensitivity. The label was detected by autoradiography (X-ray film) or by Geiger-Mueller or scintillation counting. The use of radioactivity hampered the widespread implementation of these techniques in laboratories concerned with routine testing. Subsequently, nonisotopic probes were developed that are stable for long periods (1 to 2 years). Large (microgram) amounts of DNA can be labeled at a time, allowing for multiple tests from the same lot of labeled probe. Many nonisotopic re-

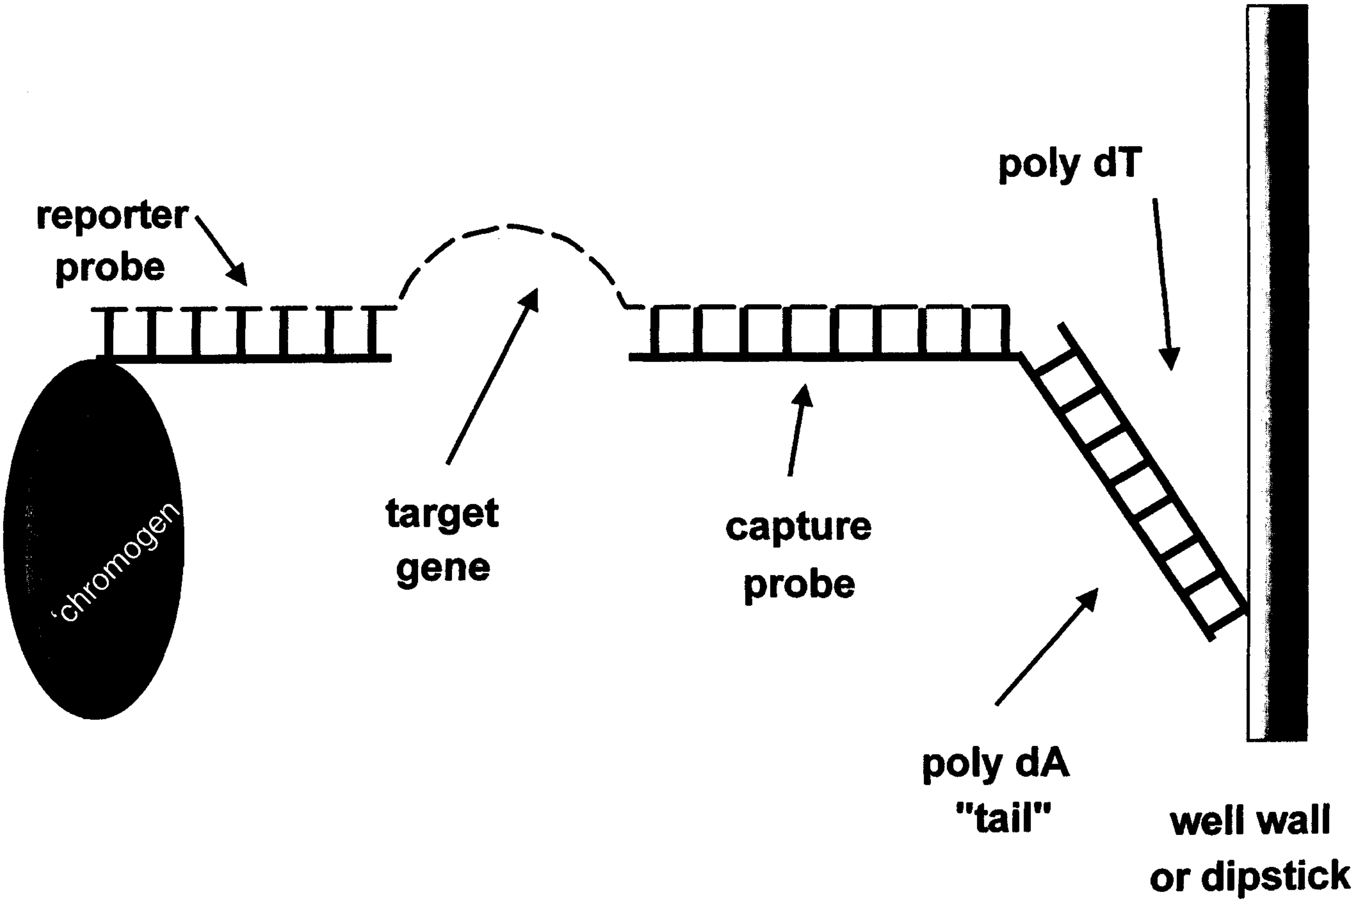

Figure 64–2 Sample Two-probe DNA Hybridization System

porter molecules are incorporated into commercially available kits. The disadvantages have been due primarily to interference from endogenous substances, which can reduce the sensitivity of the probe.

Nonradioactive indicator systems can use either direct or indirect detection. In the direct systems, bifunctional conjugates are prepared by covalently linking the oligo- or polynucleotide probe directly with the signal-generating reporter molecule. The advantage here is that only a single reaction is required for detection; however, the reporter molecule must retain its activity during the hybridization procedure. Indirect systems link a modified group to the oligo- or polynucleotide probe. After the hybridization is complete, a molecule recognizing the modified group and covalently linked to a signal-generating reporter molecule is used to detect the hybridized probe.

The most common nonradioactive nucleic acid probe-labeling systems for the detection of foodborne pathogens or PCR-amplified products have used either biotin[58,92,227,297,348] or digoxigenin.[145,164,167,188,190,191,227] Chemiluminescence is useful for quantitative detection of PCR products.[67,83,392] The direct incorporation of horseradish peroxidase[36,72,145] or alkaline phosphatase[163,259,269] to oligonucleotide probes also has been used for direct hybridization assays. The choice of nonradioactive labels depends on whether the probe is a fairly long (100 to 1000 bp) cloned fragment or a short oligonucleotide, whether the probe is DNA or RNA, and the intended hybridization format (eg, Southern blot, dot or slot blot, colony lift analysis, liquid format, or target capture). The following methods are used for labeling gene probes.

Random Primers. This method is appropriate for labeling DNA probes 100 to 10,000 bp in length. The template DNA is first purified, linearized, and denatured. Short (6 to 8 bp) random nucleotide segments, some of which are labeled with a modifying group or reporter molecule, are annealed to the template DNA to produce short regions of double-stranded DNA followed by single-stranded stretches. The Klenow fragment of DNA polymerase (the large fragment of the *E. coli* DNA polymerase that does not have 5' → 3' exonuclease activity) synthesizes a complementary strand incorporating the modified nucleotides. The reaction is terminated and labeled probe is precipitated and denatured for use in hybridization.[285]

Nick Translation. Template DNA is nicked with DNase; *E. coli* DNA polymerase I is used to add labeled nucleotides to the 3'-hydroxyl termini created by nicks in the double-stranded DNA. The 5' → 3' exonucleolytic activity of DNA polymerase I removes nucleotides from the 5' side of the nick and simultaneously continues to add nucleotides to the 3' termini.

3'-End Oligonucleotide Labeling of Oligonucleotides. Oligonucleotide probes generally are defined as probes of 50 bp or less. Automated DNA synthesizers allow the production of large amounts of oligonucleotides that can be labeled in several ways. Terminal transferase labels the 3'-end by adding a tail or a single dideoxynucleotide containing a modified group or reporter moiety. The 3'-end labeling reaction does not elongate past the single dideoxynucleotide.[349] A 10 to 100 bp tail can be added to the 3' end of an oligonucleotide using terminal transferase and a mixture of labeled and unlabeled nucleotides.[38,289] The long tail may improve test sensitivity but may result in nonspecific binding during hybridization.

5'-End Oligonucleotide Labeling. Oligonucleotides labeled at the 5' end leave the 3' end free to act as a primer in amplification reactions, yielding labeled products.[4]

Labeling RNA by Transcription. Linearized template is cloned adjacent to a RNA polymerase promoter site. RNA polymerase synthesizes a transcript using modified precursors to incorporate reporter molecules.[240,247]

Preparation of Labeled Copy DNA (cDNA). The avian myoblastosis virus (AMV) reverse transcriptase can synthesize a cDNA probe from a heat-denatured RNA template by using labeled deoxyribonucleoside triphosphates (dNTPs).[335]

Labeling DNA by PCR. A PCR using primers that bracket the target area of DNA is run with labeled dNTPs, which are incorporated into the product.[91,121]

Labeling by Photo-Activation. Nonenzymatic photoreactions covalently incorporate a modifying group into probe DNA via illumination at a specific wavelength. Photodigoxigenin, a digoxigenin molecule linked via a hydrophilic spacer to an azido phenyl residue, or psoralen biotin have been used.[250,316]

Other Nonenzymatic Labeling. Both single-stranded DNA and RNA can be labeled nonenzymatically with horseradish peroxidase that has been complexed with a positively charged polymer. The nucleic acid probe and the horseradish peroxidase are attracted by charge and glutaraldehyde is added to form chemical crosslinks.[284] The hybridization procedures must not inactivate the peroxidase.

64.2.5 Detection of Gene Probes

As mentioned above, detection of radioactive gene probes was originally done by autoradiography and occasionally by scintillation counting or Geiger-Mueller tube counting. However, detection methods for nonisotopic labels are more varied.

Depending on the type of probe label, either a direct or indirect detection procedure is used. Affinity-based reporter molecules such as biotin or digoxigenin are detected via indirect methods. Following hybridization, antibodies covalently linked to enzymes such as alkaline phosphatase or horseradish peroxidase (in the case of biotin, streptavidin is used instead of an antibody) are introduced and bind specifically to probes. Unbound molecules are washed away. Then, colorimetric or chemiluminescent substrates are added. Colorimetric substrates often consist of 5-bromo-4-chloro-3-indoyl phosphate (BCIP)/nitroblue tetrazolium (NBT) solutions where results are developed in place. Chemiluminescent dioxetene substrates are cleaved by alkaline phosphatase to give a localized light emission detected by exposure of X-ray film. This improves sensitivity and multiple exposures can be made. In a study comparing methods for the quantitation of PCR-produced DNA, electrochemiluminescence was 10 to 100 times more sensitive than ethidium bromide fluorescent staining.[392]

64.3 THE BASIC POLYMERASE CHAIN REACTION (PCR)

64.3.1 Description

Several review articles and books describe the mechanism of the PCR and other amplification reactions.[132,382] More than 10,000 papers per year are cited in MEDLINE.[148]

PCR is a method for amplifying a given region of DNA by using a pair of specific oligonucleotides that bracket that region and serve as primers for polymerase to initiate DNA replication (Figure 64–3). This section is copied repeatedly. The template DNA strands are separated by heating and then are cooled to allow primers (at a concentration about a billion-fold greater than the template) to reform the double helix (anneal) with the template strands. The temperature at which this occurs is critical for controlling the stringency of primer binding to the template, a crucial factor in determining the specificity of the amplification reaction. Usually a third temperature is used to allow copying of the template strands (the primer extension step) to occur at the optimum temperature of the DNA polymerase, but there are many variations. The newly synthesized DNA strands serve as templates for subsequent rounds of replication; therefore, the amount of DNA created theoretically increases by a factor of 2 at each cycle. During the second round of synthesis, product strands that terminate in primer sequences arise; these defined-end molecules increase exponentially in subsequent cycles, becoming the predominant product. These molecules can be detected and quantitated by gel electrophoresis followed by ethidium bromide staining, ultraviolet light illumination, and colorimetric reactions or chemiluminescence. The high specificity possible with PCR arises because it is a hybridization method using two gene probes; the amplification is achieved by repeating the hybridization 30 to 40 times.

Initially, PCR was performed by moving tubes manually among three heating blocks or water baths and, because the DNA polymerase was inactivated by the denaturation step, fresh enzyme had to be added during each cycle. To increase the usefulness and convenience of PCR, the technique was automated. While a programmable heating and cooling block was relatively simple to develop, a critical feature was the use of a thermally stable DNA polymerase from the thermophilic microbe *Thermus aquaticus* (*Taq* DNA polymerase).[43]

All components necessary for PCR analyses are now available commercially, including reaction buffer, $MgCl_2$, the four deoxyribonucleotides (dATP, dTTP, dCTP, and dGTP), and several thermotolerant DNA polymerases. Oligonucleotide primers specific for a selected genetic target sequence can be prepared commercially according to customer specifications. Assembling and using individual PCR components allow analysts to optimize a system for their specific needs. However, a complete PCR kit for amplification of unique *Salmonella* gene sequences from preenriched food samples of fluid or dried milk, chicken, turkey, beef, and pork has been introduced (DuPont, Wilmington, DE).[165,169] The primers, polymerase, and nucleotides are lyophilized into a tablet at the optimum concentrations and packaged within tubes for PCR amplification. The DNA from the enriched food sample is prepared with lysis solution and added to the PCR amplification tubes. Control tubes containing *Salmonella* DNA are used to detect DNA replication inhibitors. The amplified product is detected by gel electrophoresis. Kits for the PCR detection of *E. coli* O157, *Listeria* species, and *L. monocytogenes* have become available.

64.3.2 Sensitivity

It is important to determine the sensitivity of PCR-based assays for the detection and identification of foodborne microorganisms; however, no standard has been adopted for the determination and reporting of sensitivity. If PCR-based methods are to be adopted, they will most likely need to receive the Association of Official Analytical Chemists International's (AOAC) approval or the equivalent and, therefore, will be compared with standard methods. This will require that sensitivities be calculated as the number of bacterial cells detected per 25 g of sample. Now, many authors report the sensitivity in picograms of DNA; to evaluate the relevance of these data, they should be converted to number of microorganisms, a more biologically meaningful quantity. If most bacteria have a genome approximately the size of that of *Escherichia coli* (about 5 fg), then 1 pg of DNA is equivalent to about bacterial 200 genomes, and 1 ng represents about 2×10^5 bacterial cells.

64.3.3 Fidelity

For PCR-based detection methods, high-accuracy replication of DNA may not be required. The primary determinative step of these assays is whether the amplified product is of the expected size. During test development, the genetic information of the amplicon may be verified by restriction endonuclease digestion, further amplification with nested primers, hybridization with a gene probe targeted to a region within the amplicon, or by nucleotide sequencing. However, during routine use of these PCR

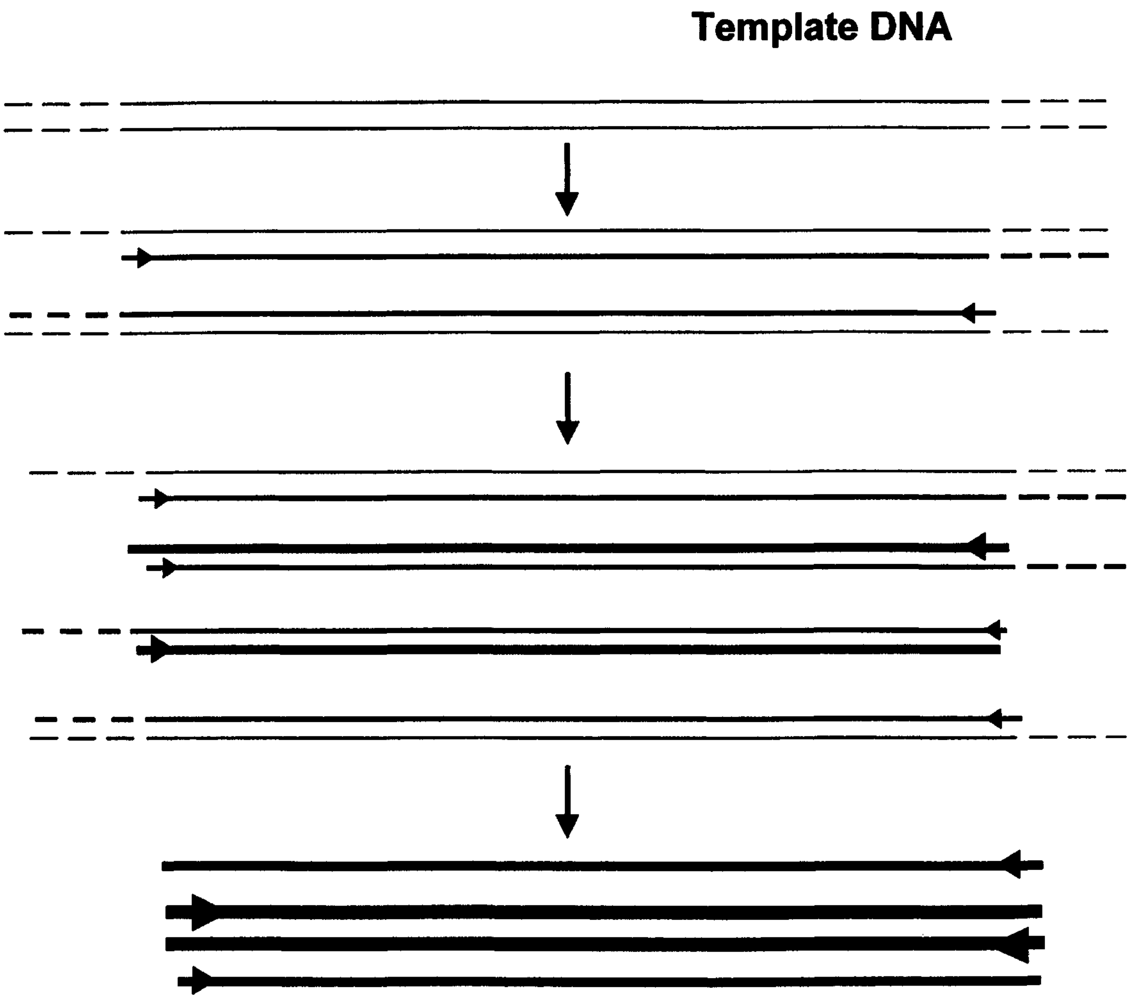

Figure 64–3 The Polymerase Chain Reaction. Segments with arrows represent primers. The thicker lines represent more recently synthesized strands. Courtesy of R. Myers.

tests, further characterization of the amplicon usually is not carried out.

For cloning or for collecting nucleotide sequences for strain comparison, high-fidelity DNA replication is more important. Several thermostable enzymes have putative proofreading activity (*Pfu*, Deep Vent, *UlTma*) and reduce errors during replication. Replication accuracy is influenced by several factors, including the insertion of the wrong nucleotide; proofreading by a 3' → 5' exonuclease can lead to removal of mismatches followed by repair extension. For the *Taq* polymerase, the error rate per base pair ranges from 1.1×10^{-4} [341] to 2.0×10^{-5}.[228] Deletion of the N-terminal end of this enzyme reduced the error rate to about 5.1×10^{-5}, an improvement of about a factor of 2.[16] Similar results were obtained using a yeast transformation assay.[106] These rates appear to be considerably higher than those estimated for in vivo replication and, when propagated over 30 to 40 amplification cycles, could allow significant errors to accumulate. If ambiguous results are obtained, it is recommended that nucleotide sequences should be determined from DNA independently amplified from several lots of starting material.

64.3.4 Selection of Primers

Computer software has been developed to search for sequences that fulfill particular criteria,[315] but the final test of primer effectiveness often is determined empirically. To develop a test with high specificity, primer sequences should be unique and targeted to a single region. The similarity of a proposed region to other sequences can be determined from databases such as GenBank® or that compiled by the European Molecular Biology Laboratory (EMBL) by using specially designed software.[6,270] This process does not ensure that the primer regions are unique but it does provide some confidence that the sequence(s) is not common, or that it does not share sufficient homology with other regions to be nonspecific.

Another important factor is the estimated denaturation ("melting") temperature of the template-primer hybrids and the selection of the appropriate annealing temperature for the PCR. Again, software can assist in finding segments with suitable T_m (melting) or T_d (dissociation) temperatures;[156,226,294] such programs usually check for hairpin loops, primer self-complementarity, and complementary regions between pairs of primers to reduce the formation of primer dimers. Primers with GC rich 3' ends (a "clamp") appear to establish more stable sites for the initiation of polymerization; however, a run of three or more G or C bases in the 3' position could stabilize nonspecific primer annealing. In the selection of primer sequences, characteristics of the amplified region such as size or the location of restriction endonuclease sites should be considered.

64.3.5 Optimization of Reaction Conditions

Although the basic PCR is fairly simple, several parameters have a major effect on its specificity and efficiency.[299,300] Divalent cation concentration, pH, primer sequence and concentration, hybridization stringency (as influenced by annealing temperature), number of cycles of replication, time of elongation cycle, and the size of the amplified fragments are important.[71,158] The annealing temperature and the salt concentration affect hybridization stringency. If the annealing temperature is too low, hybridization stringency is reduced; nonspecific priming may occur and several regions may be amplified. The temperature of annealing is particularly important during the early replication cycles as disparate regions may be amplified.[291] To minimize false priming during the first cycle, the polymerase can be separated physically from the other reaction components by wax. This separation prevents extension below the annealing temperature because the wax melts during the initial denaturation step allowing the polymerase to combine with other components.

A further procedure to prevent nonspecific priming uses an initial annealing temperature above that required for primer binding; the temperature is lowered for each successive cycle until a product is formed.[84] Heating before amplification may also increase the specificity of the reaction.[71] By holding the reaction at a higher temperature, the annealing of primers with each other (primer dimer formation) may be reduced. This is important because primer concentrations should remain high compared with that of the template. Preamplification heating may encourage a higher stringency of primer annealing during the first cycle of elongation. If short regions of DNA are being amplified, a lower denaturation temperature may increase the amount of product.[389] A procedure for calculating annealing temperatures has been advanced.[295] Although algorithms for estimating annealing temperatures provide a starting point, empirical results usually govern the selection of parameters.

The PCR is influenced by divalent cation concentrations and, for each set of primers, the magnesium ion concentration should be optimized for priming specificity and amplification efficiency. For most sets of primers, 1 to 6 mmol $MgCl_2$ l^{-1} is the optimum range. Concentration artifacts range from no product to the generation of several amplicons, ostensibly caused by a decrease in the specificity of the enzyme for the primer-template hybrids. Template concentration can also have a pronounced effect: if too high, the large numbers of variable-length copies produced usurp precursors so that the target region will not be replicated efficiently, leading to a false negative result or smears of PCR product observed after gel electrophoresis. An excessive number of amplification cycles can also generate variable-length molecules and thus decrease the amount of the specific product.[26]

64.3.6 Prevention of Carryover Contamination

Completed amplification reactions may contain billions of copies of molecules that include complementary primer sequences on each end. Because a single region of template DNA can be amplified many million-fold, PCR products must be considered much like infectious agents that can "contaminate" future reactions; therefore, it is important to minimize cross-infection. Physically separate areas and liquid handling equipment can be used for setting up reactions and for analyzing amplified material. Aerosol-reducing pipet tips and positive-displacement micropipetors help to reduce cross-contamination. Liquid handling should be kept to a minimum by making master mixes of reagents to further reduce the possibility of adulterating reactions.[205] Ultraviolet light will crosslink any stray DNA and prevent it from being replicated.[62] Another ingenious method to reduce carryover of amplified product into subsequent reactions uses uracil incorporation. Ensuing reactions are treated with uracil DNA glycosylase that cleaves uracil-containing DNA;[223] this DNA cannot function as template. The enzyme is inactivated by heating before carrying out amplification. Rys and Persing[296] compared three methods to inactivate amplified product and eliminate carryover contamination: post-PCR product cross-linking with isopsoralen, the treatment of dU-containing products with N-glycosylase, and hydrolysis of PCR products incorporating 3′ ribose-containing primers. These methods were all capable of inactivating 10^4 to 10^9 copies of amplified product.

64.4 GENERAL ASPECTS OF APPLICATION OF THE PCR TO DETECTION OF MICROORGANISMS IN FOOD SAMPLES

64.4.1 Preparation of Samples

The application of PCR to the detection of microorganisms in food requires efficient template preparation. It appears to be much easier to prepare DNA adequate for hybridizations than to prepare efficiently amplified template DNA. Food samples vary in composition and consistency; they may have low numbers of target organisms and high numbers of other microorganisms. Thus, they more often present sample preparation problems than do clinical samples. An internal control for amplification is important when samples may contain PCR inhibitors.[375] A conserved region of the 16s rRNA gene serves this purpose well.

Enrichment culture is often used before the PCR. Although an enrichment step lengthens the time of analysis, it dilutes inhibitors in the food and increases the number of target organisms.[7,23,109,119,152,174,321,369] Enrichment may induce the loss of genetic elements, particularly those on plasmids; therefore, it may be advantageous to omit or minimize enrichment.[206] Centrifugation and washing techniques can concentrate target organisms and remove some PCR inhibitors.[65,282,366,378] Filters and flow cytometry can concentrate bacteria from water and other samples.[175,303] Another strategy to concentrate organisms is antigen capture. For example, immunomagnetic separation (IMS) uses super-paramagnetic particles or beads coated with antibodies against surface antigens to "capture" specific target microbes and remove and concentrate the organisms. Both polyclonal and monoclonal antibodies have been employed. The antibodies can be attached to the beads either directly or indirectly, via primary antibodies covalently attached to the beads. IMS techniques are reviewed elsewhere[263] and have been used to detect a variety of foodborne pathogens including *L. monocytogenes*,[109] enteropathogenic *E. coli*,[157] *E. coli* O157,[174] *Salmonella*,[110,372,373] *Shigella dysenteriae* type 1 and *Shigella flexneri*,[161] *Yersinia enterocolitica*,[183] and *Cryptosporidium* oocysts.[175]

PCR inhibitors are a significant problem in many types of samples. Various strategies have been used to overcome their effects. For example, trace amounts of inhibitory humic substances in soil samples[346] have been removed by gel filtration.[345] Chelex resin[52,180,198] and various commercially available columns are used to bind potential PCR inhibitors.

Once the target organisms have been concentrated and inhibitors removed, the DNA must be available in an amplifiable form. Boiling is often used to release DNA from microorganisms. Other methods include phenol-chloroform DNA extractions, enzymes (eg, proteinase K), sonication, heating with microwaves, and thermal shock.[272] Guanidinium isothiocyanate and other chaotrophic agents assist in the disruption of cells and release of the DNA.[131,152,180,233] Columns[7] and DNA precipitation[42,119,186,233] have been used to purify and concentrate DNA.

64.4.2 Detection of Viable But Nonculturable (VBNC) and Dead Organisms

Tests for microorganisms in food are concerned almost exclusively with viable organisms. Because PCR methods may amplify DNA from dead microorganisms,[237] there is a need to assess whether the target organisms are viable. Because dead cells may contain amplifiable DNA, incubation of a sample for a short period and demonstration of an increase in product amplified by PCR has been used as evidence of the viability of target organisms.[206] Appropriate controls are necessary to detect the presence of any amplification inhibitors.

VBNC cells of some pathogens[290] might pose a health hazard if not detected by culture, but conflicting results exist regarding PCR detection of VBNC cells.[22,162,181] The effect of stress treatments such as starvation, acid, heat, H_2O_2, or desiccation on the detection of *L. monocytogenes* and enterotoxigenic *E. coli* (ETEC) by PCR have been studied.[237] The type of stress to which cells were exposed affected the relationship between plate count and detection by PCR. Exposure to acid or to H_2O_2 resulted in a rapid reduction of plate count and detectability by PCR; however, starvation and heat (including exposure to 100° C temperatures and autoclaving) that caused a rapid reduction in plate count did not result in a rapid loss of detectability by PCR. *Vibrio vulnificus* can be difficult to isolate from the marine environment during the cooler months when it may be in a VBNC state; however, this state can be reversed by resuscitation. When *V. vulnificus* cells were treated in the laboratory to render them viable but unable to form colonies on plating, they were more difficult to detect by PCR than predicted.[41,256] This may have been because the DNA had accumulated single-stranded nicks, rendering it a poor template for PCR but not greatly affecting viability.

Another way to demonstrate viability of the target organism is by using mRNA, which has a shorter functional half-life than DNA, as a template (see the section on reverse transcriptase [RT] PCR). When purified mRNA was used to generate cDNA in an RT-PCR, for the *ctx* gene of *V. cholerae*, no amplification was observed when nonviable cells were tested.[246] The method by which *Giardia* cysts were killed affected detection by RT-PCR.[231] Freezing prevented PCR amplification of mRNA, but heat-treatment or exposure to monochloromine did not.[231] The amount of total RNA and giardin mRNA recovered from live cysts increased after excystation. Therefore, either measuring total RNA or performing RT-PCR for giardin mRNA before and after excystation can be used to distinguish between live and dead cysts.[231] Similarly, *Cryptosporidium* oocysts could be detected by induction of excystation to provide intact, amplifiable DNA and demonstrate viability.[103]

In some instances, the PCR amplification of DNA in the absence of viable cells could be important. PCR detection of staphylococcal enterotoxin genes might predict the presence of the enterotoxin(s) in samples although thermal processing may have killed the vegetative cells.[378]

64.4.3 Detection of PCR Products

Detection is based primarily on the observation of an appropriately sized product visualized by UV illumination of ethidium bromide-stained gels. PCR assay sensitivity and specificity have been enhanced in many protocols by employing more sensitive methods for the detection of amplification products. Methods that are more sensitive usually involve gene probes to the amplified region. The amplified product may be spotted onto a solid support, such as a membrane, and followed by gene probe hybridization.[21,29,42,51,77,110,157,167,175,207,261,268,320,359] Alternatively, a probe can be affixed to either a membrane or a microtiter well to "capture" the PCR amplicons that are then detected with a second "reporter" probe.[52,118] A "reporter" molecule such as digoxigenin-11-dUTP[164] or a biotin-labeled primer[320] can be incorporated into the amplicon during the PCR process.[227] When these amplicons are captured, they can be detected directly without the use of a second "reporter." When both biotinylated primers and digoxigenin-dUTP are incorporated during PCR, the amplification products can be captured by streptavidin-coated microtiter wells and detected by antidigoxigenin-alkaline phosphatase conjugate.[227]

An oligonucleotide ligation assay (OLA) can detect PCR amplified products from *Salmonella*.[325] Following amplification, the product was denatured and oligonucleotide probes targeted to adjacent regions were hybridized to the amplified DNA. One probe was biotinylated on the 5' end and referred to as the "capture probe"; the "reporter probe" was labeled with digoxigenin on its 3' end. Ligation between the two probes was accomplished if there was complete complementarity. The ligated probe complex then was captured on streptavidin-coated microtiter wells where the reporter molecule was detected after the addition of a chromogen-substrate complex.

An alternative approach uses a fluorescently labeled internal probe and a quencher dye coupled to individual nucleotides near to each in the primer; fluorescence is reduced because these moieties are close. This internal probe anneals to the template but the *Taq* polymerase's 5' → 3' nuclease activity digests the internal probe during the extension step of each cycle. Therefore, the quenching dye is removed from its nearby location so fluorescence is increased and is proportional to the amount of the PCR product.[17]

Blais and Phillippe[36] describe the use of an unlabeled RNA probe complementary to the amplified *Listeria hlyA* fragment and a polyclonal anti-RNA-DNA IgG antibody peroxidase conjugate to increase the sensitivity of detection of amplified PCR product compared with agarose gel electrophoresis. This approach was refined further by using one PCR primer containing a T7 RNA polymerase promoter.

The amplified product was transcribed using T7 RNA polymerase and the RNA transcript captured by a DNA probe immobilized on microtiter wells. An immunoenzymatic assay with anti-RNA-DNA antibodies was used to detect as little as 0.15 ng of amplified product representing a 10-fold improvement over gel electrophoresis.[35]

64.5 MODIFICATIONS OF THE BASIC PCR METHOD

Several modifications of the original PCR procedure have been reported that might be applied to testing foods.

64.5.1 Multiplex PCR

Multiple sets of PCR primers are used concurrently within the same reaction tube to amplify simultaneously several regions of a target genome.[24,25] Some interaction may occur among the primer sets so primer concentrations might have to be adjusted to produce reliable yields of all the PCR products.

64.5.2 Nested PCR

It is possible to dilute the impact of template contamination with previously generated PCR products and reduce the effects of PCR inhibitors by carrying out two serial PCRs. When the first PCR is completed, between 0.01 and 1 µl of the reaction mixture is used as template for a second PCR. A second set of primers targeted to sequences on the 3' sides of the original primers generates a second, slightly shorter product.[279] A modification of the multiplex and nested primer PCR involves three primers targeted to the same gene to provide additional confirmation.[51] For example, the two "forward direction" primers and one "reverse" primer may result in two amplification products, reducing the risk of nonspecific amplification.

64.5.3 Inverse PCR

Ordinarily, the nucleotide sequence or the restriction endonuclease sites of the region to be amplified are known. When primers are made so that their 3' ends extend away from each other and the template DNA is cleaved with a restriction enzyme distal to this region and then circularized by DNA ligase, the unknown genetic sequences outside the region can be amplified and sequenced.[260,343]

64.5.4 Mismatch Amplification Mutation Assay (MAMA)-PCR

This method can distinguish between targets that differ by only one nucleotide.[56] Primers are constructed so that the 3' end of one of the primers contains a single mismatch with the allele to be detected and a double mismatch with the allele to be excluded. Thus strains of bacteria that differ by a single nucleotide in the amplified region can be detected and differentiated (Figure 64–4).[55]

64.5.5 Quantitative PCR

It is difficult to estimate the initial concentration of the template in the reaction from the amount of PCR product synthesized. A small difference in reaction efficiency can result in a substantial difference in the amount of the final product. One method to estimate the initial concentration of PCR template requires the concomitant amplification of a control molecule of known starting concentration and then a comparison of the final concentration of each product.[19,40,64,126,143,254] There is some uncertainty in this type of measurement, because there can be differences in amplification efficiency associated with the different primers or with the nature of the amplified region itself. This problem might be minimized by using the same primers to amplify a control region that would be distinguished from that of the unknown by differences in length or restriction endonuclease sites. The control templates could be added directly into a sample to ascertain whether PCR inhibitors are present by comparing the amounts of the products.[64]

Limiting dilution can be used to calculate the initial number of PCR templates in a sample.[326] This would determine the most probable number (MPN) of detectable PCR templates. A direct comparison of the MPN of microorganisms detected by a cultural method and the MPN of templates detectable by PCR can be made. (The statistics of MPN counts are covered in Chapter 60.)

64.5.6 Reverse Transcriptase PCR

When an RNA template (such as some viral genomes or mRNA) is to be amplified, a strand of DNA (cDNA) is made using RT and the "downstream," or "reverse" primer (Figure 64–5). The cDNA can then serve as a template for a standard PCR.

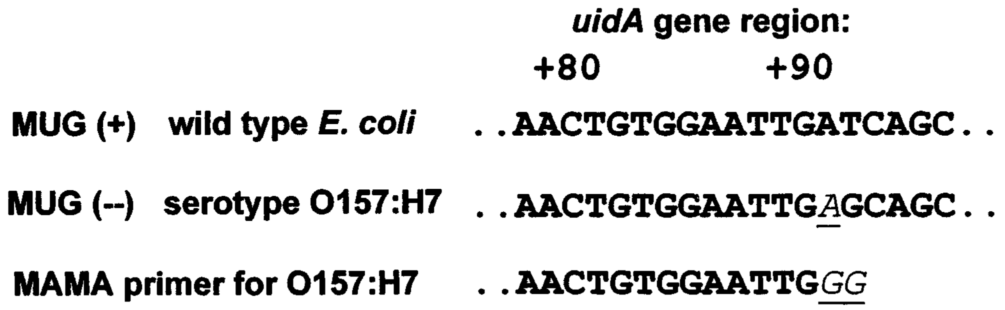

Figure 64–4 Mismatch Amplification Mutation Assay Used to Detect *Escherichia coli* O157:H7. The primer for amplification of *E. coli* O157:H7 DNA contains one mismatch at the 3′ end with the intended target, but two mismatches with the genotype to be excluded. This allows preferential amplification of the O157:H7 target over another template that differs by a single basepair.[55] *Source:* Adapted with permission from T.A. Cebula, W.L. Payne, and P. Feng, Simultaneous Identification of Strains of *Escherichia Coli* Serotype O157:H7 and Their Shiga-Like Toxin Type by Mismatch Amplification Mutation Assay-Multiplex PCR, *Journal of Clinical Microbiology*, Vol. 33, pp. 248–250, © 1995, American Society for Microbiology.

64.5.7 Degenerate Primers

The exact nucleotide sequence of a region may not be known or the identity of some nucleotide positions may be ambiguous (this might be the case if only the amino acid sequence of the encoded protein is available). In some cases, these difficulties can be overcome by synthesizing an oligonucleotide containing deoxyinosine in these positions[50,235] or by allowing more than one nucleotide at a particular spot creating a pool of mixed (degenerate) sequence molecules.

64.6 NON-PCR-BASED AMPLIFICATION METHODS

Three examples of such systems are described here briefly because they do not employ thermocycling and may, therefore, be simpler than PCR methods.

64.6.1 Self-sustained Sequence Replication (3SR) or Nucleic Acid Sequence Based Amplification (NASBA™)

This method uses a single temperature with a primer, an RNA template, and RT to generate a cDNA intermediate containing a bacteriophage T7 promoter (Figure 64–6).[94] RT makes a cDNA copy of the target RNA and the old template strand is degraded by RNaseH. The single-stranded cDNA serves as a template for the construction of a complementary strand. From this double-stranded molecule, T7 RNA polymerase synthesizes multiple transcripts of the region downstream from the T7 promotor. The transcripts are used as templates to construct additional cDNA molecules, which are then rendered single-stranded by RNaseH. The process continues at about 42° C; neither thermostable enzymes nor thermocycling is required. Amplifications of greater than 10^8-fold within 30 minutes have been observed.

64.6.2 Ligase Amplification (Ligase PCR)

The second term is a misnomer because the amount of product increases by joining two oligonucleotides instead of by synthesis of new strands by a polymerase. Two oligonucleotides are chosen to be complementary to adjacent regions of the targeted nucleotide sequence. When the target is present, the oligonucleotides will be positioned correctly for joining by DNA ligase (Figure 64–7).[255] When two pairs of oligonucleotides are used, one pair complementary to each strand, the number of ligated molecules will double each cycle; each molecule serves as a site for the alignment of a pair of oligonucleotides. This assay detects templates differing by only

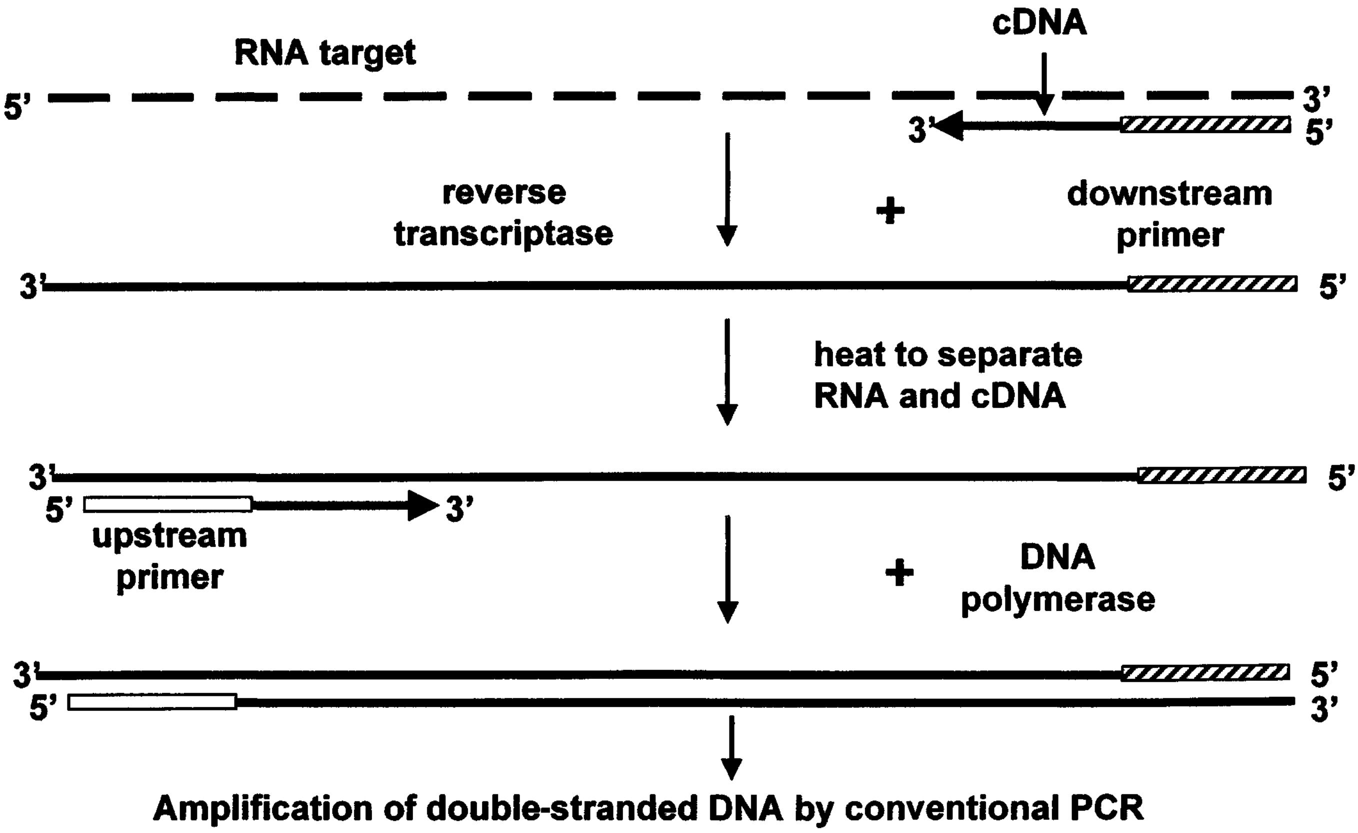

Figure 64–5 Reverse Transcriptase PCR

a single base pair when this site is located at the 3' end of the upstream primer.[15] It discriminates between *L. monocytogenes* and other *Listeria*.[374]

64.6.3 Qβ Replicase

The RNA polymerase from bacteriophage Qβ replicates RNA.[46,135,239] A detection probe, composed of a region complementary to the target and a region that can be copied by Qβ replicase, is hybridized to the target. The unbound probe is removed by hybridization to a capture probe attached to a solid support and complementary to a region amplified by the replicase. After the addition of Qβ replicase, the presence of the target nucleic acid is indicated by an increase in RNA.[202]

64.7 DETECTION OF FOODBORNE MICROBES

This section will discuss some examples of the use of genetic techniques to detect microorganisms in food. For further examples of the application of these methods, chapters on specific foodborne pathogenic microorganisms should be consulted.

64.7.1 Bacteria

Aeromonas spp. Members of this genus produce a variety of extracellular hemolysins and cytotoxins; aerolysin appears to be an important virulence factor (see Chapter 38).

Aerolysin is produced by some strains of *A. hydrophila* associated with human disease; the (*aer*) gene can be detected by PCR,[276] although its presence may not always correlate with strain virulence.[59] Similarly, Baloda et al.[14] targeted the β-hemolysin gene. Positive *A. hydrophila* strains were also hemolytic and toxic to tissue culture cells; however, hemolytic *A. sobria* and nonhemolytic *A. hydrophila* were negative by this PCR test. A 16S rDNA PCR assay detected aeromonads and, subsequently, primers were used to specifically detect *A. hydrophila* and *A. veronii*.[86] The gene for a cytolytic enterotoxin shares some similarity to *C. perfringens* enterotoxin and *L. monocytogenes* listeriolysin.[60]

Bacillus cereus. The gene encoding the enterotoxin, *bceT*, of *B. cereus* has been sequenced and may serve as the target of a PCR-based detection sys-

tem.[3] Cereolysin AB, a cytolytic protein responsible for hemolysis, has been targeted with oligonucleotide probes.[310] Although there are no reports of these procedures being applied to foods implicated in disease outbreaks, the methodology is being developed and the tools are becoming available.

***Campylobacter* spp.** A commercially available, alkaline phosphatase-labeled oligonucleotide probe specific for thermotolerant campylobacters detected all 71 *C. jejuni* and *C. coli* strains tested.[68,115] A different commercial, non-isotopic DNA probe was tested on enrichments from contaminated chicken carcasses and from feces.[323] In the enrichment about 10^6 colony forming units (cfu) ml^{-1} were required to yield a positive result.

DNA extracted from pure cultures provided template DNA for a set of *flaA* (flagellar antigen gene) PCR primers.[266] Reported sensitivity was four cells per reaction but dropped to 30 to 60 cells per reaction in seeded stools. To detect campylobacters in raw milk and dairy products, Wegmüller et al.[366] digested samples adjusted with buffer and removed the fatty acid and water layers by centrifugation. After lysing cells with proteinase K, primers to *flaA* and *flaB* genes were used to amplify an intercistronic region predicted to be between 340 and 380 basepairs (bp) long. To ensure specificity, a triple primer PCR was used (the third primer was targeted to the intercistronic region) and a seminested PCR was carried out. The limit of detection in water was between 10 to 100 cells after 50 cycles of amplification using naturally contaminated samples, suggesting that PCR-inhibiting substances were present. A three-primer, seminested PCR could detect less than 10 cells in 40 ml of raw milk or 2 g of soft cheese after rounds of 30 and 40 cycles. Environmental water samples were collected onto Fluoropore, Durapore, and cellulose acetate filters and PCR was used to test for the *flaA* gene.[265] No PCR amplification was noted with the cellulose acetate filters but sensitivity with the other filters was about 10 to 100 viable cells per 100 ml water without enrichment.

By targeting various regions of *Campylobacter* 16S rRNA, a 426 bp amplicon was observed when *C. jejuni*, *C. coli*, and C. *lari* were tested.[123] For seeded

chicken product samples, a detection limit of about 12 cfu per reaction (corresponding to 500 cfu ml^{-1} of enrichment medium) was reported and results were available within 48 hours. In a method employing PCR and specific DNA probes, Giesendorf et al.[124] targeted arbitrary sequences in conjunction with ERIC (enterobacterial repetitive intergenic consensus sequences[159]) to generate species-specific fragments for use as DNA probes.

The isothermal DNA amplification technique, NASBA™ targeted to 16S rRNA, was specific for *C. jejuni, C. coli,* and *C. lari.*[353,354] Sensitivity was about 1000 rRNA copies per reaction; when chicken skin and ground beef were seeded, 3 *C. jejuni* cells g^{-1} could be detected after enrichment, in a background of over 10^6 Gram-negative cells.

Clostridium botulinum. Because neurotoxins elaborated by *C. botulinum* (see Chapter 41) can cause severe and sometimes fatal paralytic disease, rapid detection and identification of the presence of these toxins in foods are critical. The effects of *C. botulinum* (with the exception of infant botulism) are due to the ingestion of preformed toxin. Therefore, viable cells or spores of *C. botulinum* might not be present in a food suspected of containing the toxin. Because PCR can be used to amplify the DNA of viable but nonculturable or even nonviable microbes, this method may be employed to demonstrate whether a food has been contaminated with *C. botulinum* harboring a particular toxin gene.

By targeting the 16S rRNA gene sequences, a PCR-based genus-specific method was developed with a claimed sensitivity for *Clostridium* spp. spiked into soft drinks of about 5 cells or spores per reaction.[118] Most PCR-based tests for *C. botulinum* detect neurotoxin gene sequences. Using the published amino acid sequence of the type B neurotoxin, Szabo et al.[327] selected primers but reduced their degeneracy by considering codon usage by other clostridial genes and the codon bias exhibited by the related tetanus toxin gene. A test sensitivity of 10 pg (about 2 x 10^3 cells) of *C. botulinum* DNA was achieved when PCR products were analyzed by gel electrophoresis, but using biotinylated PCR-product that was hybridized to gel blots the sensitivity was improved 100-fold.

The published nucleotide sequence of the *C. botulinum* type A neurotoxin gene[33,340] allowed primer selection for a 1.3 kilobase pair (kbp) region.[98,100] Commercially canned products were inoculated with 100 viable spores per gram. After incubation samples were centrifuged, pellets were washed in buffer and then heated at 99° C for 10 minutes to release the DNA from vegetative cells for amplification. Products were detected by dot blots by using a digoxigenin-labeled internal gene probe. Most food samples gave positive results after 1 day of incubation while others required more than 15 days. The different results obtained with some food products were probably due largely to differences in the extent to which they allowed germination of spores of *C. botulinum* and multiplication of the vegetative bacteria. The lysing procedure was probably not adequate to release DNA from nongerminated spores.

The nucleotide sequences of *C. botulinum* type B, C, D, E, and G toxin genes share about 50% sequence similarity with type A toxin and tetanus toxin genes.[371] Individual primer sets were used to detect genes encoding toxin types A, B, C, D, and E with a sensitivity of about 10 fg of isolated DNA representing about 3 cells.[328] Similarly, other primer sets for toxin gene types A, B, and E were tested.[111] A PCR-based test specific for the type F toxin gene also was developed.[101] Degenerate primers were used to amplify a 1.1 kbp region of the genes encoding toxins A, B, E, F, and G from *C. botulinum*, *C. barati*, and *C. butyricum*.[48] A degenerate primer pair was used to amplify a 260 bp region from genes that encode toxin types A, B, E, F, and G.[93] Sensitivity was 1 vegetative cell per reaction for types A and B and 10 cells for type E. In food samples inoculated with 10 vegetative cells of *C. botulinum* g^{-1}, a positive result was obtained after enrichment for 18 hours at 20° C.

Clostridium perfringens. By specifically targeting the 16S rDNA, Wang et al.[364] developed a PCR-based method specific for *C. perfringens* and capable of detecting two cells from pure culture. The PCR-based method was able to detect *C. perfringens* from enrichments of food samples initially inoculated with 20 cells per 100 g. The sequence of an enterotoxin gene from *C. perfringens* has been determined and synthetic probes developed and tested.[355] PCR-based specific amplification of the *C. perfringens* enterotoxin gene has also been carried out.[303] An enterotoxin probe labeled with digoxigenin during amplification was used in a colony hybridization assay to detect and enumerate *C. perfringens* in raw ground beef seeded with known numbers of vegetative bacteria.[12] Fewer than 10 cfu g^{-1} of the sample could be detected. Enterotoxic strains were identified by PCR-amplification of regions of the alpha-toxin and enterotoxin genes from a single colony on tryptose-sulfite-cycloserine (TSC) agar without egg yolk.[182] PCR-based detection of the enterotoxin A gene was compared with a colony hybridization method for testing irradiated and nonirradiated beef samples; the PCR assay yielded false-positive results,[13] probably because some cells unable to form colonies still contained PCR-amplifiable DNA.

Escherichia coli. Four categories of *E. coli* cause foodborne illness in humans (see Chapter 43): ETEC, enteropathogenic *E. coli* (EPEC), enteroinvasive *E. coli* (EIEC), and enterohemorrhagic *E. coli* (EHEC). This classification is based on virulence mechanisms. Many of the genetic elements responsible for virulence have been used as targets for molecular detection and identification methods, and these methods are being refined continually to improve their sensitivity and specificity. Enrichment in tryptic soy broth for 5 hours at 42.5° C, followed by a multiplex PCR to simultaneously detect and differentiate the various pathogenic strains as well as total *E. coli* from artificially contaminated ground beef, gave a sensitivity of $<10^2$ to 10^3 cells per 10 g.[221]

- ***EPEC.*** The pathogenicity of EPEC is attributed to genes present on a 55 to 70 Mda EPEC adherence factor (EAF) plasmid. A gene probe for a conserved section of this plasmid has been developed[253] and PCR amplification of a 397 bp region was reported.[112] This region had little homology with known sequences except for a section of the IS630 sequence of *Shigella sonnei*. Gene probe and PCR methods also have been used to detect the chromosomal *eae* gene cluster necessary for attachment and effacing.[170–172]

- ***EIEC.*** The invasive ability of EIEC strains is attributed to a large 120 to 140 Mda plasmid encoding several genes for outer membrane polypeptides[89] and several gene probes have been developed.[37,267,383] Lampel et al.[206] used PCR amplification of a 760 bp region of the plasmidborne invasive gene. A number of PCR template preparation methods from foods have been examined. A minimum detection level of 10^2 cfu ml^{-1} without enrichment was reported when the template was prepared by proteinase K treatment of milk followed by boiling and ethanol precipitation.[186] Columns (Promega, Madison, WI) eliminated PCR inhibitors and gave a minimum detection level of 10^3 cells ml^{-1} of milk without culturing.[7]

- ***ETEC.*** The heat-labile enterotoxin (LT) is immunologically related to cholera toxin. The LT genes (*elt*) are plasmid-encoded and present in both human (LTH or LT1) and piglet (LTp or LT2) strains. The heat-stable enterotoxins (ST) are low molecular weight, nonantigenic, and are also plasmid-encoded. The STaI and STaII forms are usually of human or animal origin while the STb form is commonly from porcine sources.

Colony blot hybridization can detect single genes or combinations.[147,155,297,311] Combinations of oligonucleotide probes to individual genes or alleles that respond similarly under the same hybridization conditions can be used for the simultaneous detection of various genetic sequences.[155,311] Oligonucleotide probes labeled with either ^{32}P or digoxigenin had approximately equal sensitivity for colony blots from stool samples spiked with 10^6 to 10^8 cfu g^{-1}, provided colony-lift filters were proteinase K-treated prior to hybridization with the digoxigenin-labeled probe.[311] A fused gene probe has been used to detect ETEC harboring the genes for either LT or ST or both.[297] Unique sequences from *estA* and *estB* genes (for ST) were cloned into a plasmid, which was linearized and transcribed with RNA polymerase to incorporate radioactive or biotinylated ribonucleotides into a single, hybrid RNA probe.

PCR methods have also been developed to detect LT and/or ST genes of ETEC. Enrichment culture prior to PCR amplification yielded sensitivities as low as 3 cfu initially inoculated into 25 g of minced meat.[368] When PCR amplification was applied directly to food samples without enrichment, 1,000 cfu g^{-1} soft cheese were detected.[5] Some approaches to improve PCR assay sensitivity include immunomagnetic selection,[157] enrichment,[368] ion exchange chromatography,[261] and gene probes to detect PCR products.[49,157,261,359] Nested PCR distinguished between the ST1a and ST1b alleles.[157] The first PCR amplified a 147-bp region for either ST1a or ST1b while the second PCR used two different primer sets to amplify a 124-bp fragment to specifically detect ST1a or ST1b. Restriction fragment length polymorphisms (RFLP) are used as an alternative method to distinguish between different alleles of the LT1 and ST1 enterotoxin genes.[49]

- ***EHEC.*** The serogroup most commonly associated with EHEC illness to date in humans is O157:H7 (see Chapter 43); therefore, many EHEC tests are specific for this serogroup. The O157:H7 serogroup often is characterized by its inability to use sorbitol and the lack of a functional b-glucuronidase; however, recent reports have described b-glucuronidase-positive strains (see Chapter 43). A base substitution at position 92 in the *uidA* (b-glucuronidase) gene has been identified as specific for *E. coli* O157:H7 serotype, although this base substitution does not cause the lack of b-glucuronidase activity.[96] This distinction provides a target for genetically based tests specific for *E. coli* O157:H7.

A 3.4 kbp segment of a 60 MDa plasmid containing genetic elements involved in adherence is common to most members of the O157:H7 serogroup.[222] The EHEC *eae* gene encodes an invasin that may also contribute to virulence.[225] The *eaeA* gene of O157 EHEC was cloned and sequenced.[20,224,393] The first 2.2 kbp exhibits 97% sequence homology with the EPEC *eae* gene but the sequence similarity in 800 bp of the 3' end is only 59%. The EHEC *hlyA* and *hlyC* genes have sequences unique to EHEC strains[306–308] and a number of genetic probes and PCR methods for the detection, identification, and/or characterization of EHEC target these genetic elements.

Poly- and oligonucleotide probes have been developed to detect the *slt*, EHEC *eaeA*, *uidA*, and/or EHEC plasmid genes.[30,31,66,122,304,312,338,339,342,376,377,380] For example, Samadpour et al.[304] used shiga-like toxin (SLT) I and SLT II probes to test oyster and raw hamburger. A minimum initial inoculum of 1.3 cfu O157:H7 g^{-1} of food sample was detected after enrichment for 16 to 24 hours at 37° C in modified tryptic soy broth (mTSB) followed by streaking to mTSA and colony hybridization or dot-blot from the enrichment. Although dot blot analysis was faster (no time was needed for colony growth), it did not allow recovery of the specific isolate from the food sample. Probes were used to screen raw meat, poultry, and seafood samples, after cultural enrichment, for *sltI* and *sltII* genes;[90,377] both studies reported the detection of the *slt* genes in 17% of the food samples tested.

Because multiple genetic elements are involved in the pathogenicity of EHEC organisms, multiplex PCR analyses have often been used to simultaneously screen for several genetic elements.[114,154,278,329,380]

The ability of PCR to detect *slt* genes in DNA extracted from stool samples was compared with colony blot hybridization, assays for free SLT, and with cultural methods for EHEC detection.[282] A minimum detection level of 10^3 and 10^4 cfu g^{-1} was reported when the bacteria were separated by centrifugation and washed prior to DNA extraction and PCR analysis. To detect EHEC in stool samples by multiplex PCR, bacteria were lysed by heating and proteinase K, DNA was extracted with phenol-chloroform, precipitated with ethanol, and purified with silica particles.[42] After ground beef inoculated with EHEC was incubated for 6 to 24 hours in mTSB, DNA was extracted using proteinase K and Sarkosyl and precipitated with sodium acetate and ethanol to prepare a template for a multiplex PCR for detecting *slt* genes. A minimum detection level of 1 cfu g^{-1} in the original meat sample was reported.[119] To detect *E. coli* O157 seeded into several types of food, the foods were homogenized in a selective enrichment medium and incubated at 37° C for 6 hours, during which time the number of target cells increased 5×10^3-fold.[174] The bacteria were either separated by centrifugation, washed, and resuspended in distilled water, or concentrated by using immunomagnetic beads. A multiplex PCR to detect fragments of the *sltI* and *sltII* genes had a sensitivity of about one cell g^{-1} of the original food. The sensitivity and specificity of PCR analyses have also been improved by various hybridization formats used to detect PCR-amplified products.[21,42,164,207]

In some PCR analyses, the primers are not selected to achieve specificity for particular genetic regions and the specificity is determined after PCR amplification. A degenerate set of PCR primers was selected from conserved regions of the *sltI* and *sltII* genes;[184] internal oligonucleotide probes that shared only 30% sequence homology then were used to distinguish between amplified product from the *sltI* and *sltII* genes. RFLPs were used[292,293,350] to distinguish between *sltII* and an *sltII* variant in PCR-amplified products.

The use of a MAMA to detect *E. coli* O157:H7 was described earlier and shown in Figure 64–5. When multiplexed with primers for the *sltI* and *sltII* genes,[55] this PCR detected *slt* gene-containing O157 strains.

Listeria. Of the six species comprising the genus *Listeria*, only *L. monocytogenes* is considered an important foodborne pathogen for humans (see Chapter 44). A number of molecular detection and identification methods using several targets have been reported for both the *Listeria* genus and specifically for *L. monocytogenes*.

A cloned DNA fragment based on a putative hemolysin gene was used by Datta et al.[74] as a probe for colony hybridization to enumerate *L. monocytogenes* in naturally contaminated dairy products. An oligonucleotide also based on the sequence of this region was used to detect *L. monocytogenes* in artificially contaminated raw milk and soft cheeses.[73] The DNA fragment later was shown to be part of the sequence designated the *msp* gene. This gene encodes a major secreted polypeptide of approximately 60kDa,[107] which also is called *iap* (invasion-associated protein).[204] The *msp* gene is conserved among *L. monocytogenes* strains, and probes for the *msp* gene, when used under stringent conditions, are specific for *L. monocytogenes*.[201] The fragment used by Datta et al.[73] was labeled with digoxigenin by the random primer technique and used in colony hybridization.[190]

Gene probes for *L. monocytogenes* based on the listeriolysin O gene also have been developed;[75,220,241] highly stringent hybridization conditions are required for specificity. An oligonucleotide probe[75] was applied to colony blot hybridization from ground beef samples.[245] Probe efficiency was dependent on the ability of the plating media to suppress background growth and the stringency of hybridization conditions. An oligonucleotide probe labeled with horseradish peroxidase was less sensitive than the radioactive labeled probe.[72] Herman and DeRidder[145] compared oligonucleotide probes for listeriolysin O and *iap* genes to detect *L. monocytogenes* in soft cheese; these probes were labeled either directly by coupling to horseradish peroxidase or by incorporation of digoxigenin but both produced background signals. Partial success with the digoxigenin system was reported after excess cellular debris was removed from the colony blots by rubbing with a soft paper soaked in 5XSSC solution.

The first commercially available gene probe product (GeneTrak) for *Listeria* spp. used a ^{32}P labeled synthetic probe.[195] The Gene-Trak Isotopic Assay and the US Food and Drug Administration (FDA) cultural method gave comparable results with spiked food samples but the Gene-Trak method was less sensitive when applied to naturally contaminated seafood samples.[238] A colorimetric version of the Gene-Trak gene probe hybridization is now available.[192] A 5.9% false-negative rate for the Gene-Trak system was reported with 250 naturally contaminated cheese and environmental samples, compared with the International Dairy Federation cultural method.[351] This may have been because the numbers of *Listeria* from samples may not have reached the minimum detection limit for the hybridization (10^6 cells ml^{-1}) during the cultural enrichment step.

Using a second commercially available kit (AccuProbe *L. monocytogenes*), the minimum detection level for bacteria resuspended in physiological saline is 10^5 cfu in 50 µl. A minimum of 10^6 cfu per 50 µl was required for samples from three different nonselective enrichment broths and the FDA *Listeria* enrichment broth. The broths UVM-I, UVM-II, and PALCAMY interfered with the hybridization.[257] Tests of 44 *Listeria* isolates resulted in the correct identification of all *L. monocytogenes* isolates and perfect correlation between a slot-blot hybridization using the probe developed by Datta et al.[72] and the AccuProbe *Listeria monocytogenes* kit.[176]

A region of the spacer between the 16S and 23S rRNA genes was specific for *Listeria* species with a minimum detection level of 5×10^2 cells ml^{-1} in artificially contaminated meat homogenates without enrichment.[92] Hybrids between *Listeria* rRNA and a biotinylated rDNA probe in an aqueous environment were captured by monoclonal antibodies to heteroduplex DNA.

PCR analyses have been developed to detect one or more genes specific either for *L. monocytogenes* or for all *Listeria* spp. The most common target is the *hylA* gene encoding listeriolysin O.[17,29,35,36,79,104,109,128,144,220] This target also has been used in multiplex PCR analyses.[39,51,65,99,116,178,210] Other virulence-related targets specific for *L. monocytogenes* include the *iap* gene,[44,51,99,116] the Dth-18 gene,[220,369] *prfA* and *plcB*,[65] and hemolysin genes.[116,220] Other genes specific for *L. monocytogenes* but not necessarily virulence-associated have been used.[57,176,220,287] The 16S rRNA gene is another PCR target either for detection of all *Listeria* spp.[39,210] or specifically for *L. monocytogenes*.[208,365]

Test sensitivity can be improved when applying PCR methods to foods for the detection of *Listeria* by a variety of template preparation protocols.[65,109,144,208,234,369]

PCR sensitivity was improved by the use of short denature and anneal times with a rapid transition and an increased number of cycles enabling detection of 4 to 40 cfu g^{-1} inoculated into diluted food samples that were not enriched.[365]

Other methods have been developed to improve PCR sensitivity. These include nested PCR,[167] internal DNA gene probes,[29,167] RNA probes,[35,36] and the degradation of an internal probe during the amplification process (see Section in 64.5).[17] The ligase chain reaction discriminates between *L. monocytogenes* and other *Listeria* spp. based on a single basepair difference in the V9 region of the 16S rRNA gene.[374]

Salmonella**.** Methods have been designed to detect the genus *Salmonella* because most species are associated with illness in humans. One of the first hybridization tests used a ^{32}P-labeled probe for chromosomally located *Salmonella*-specific sequences.[105] This probe was used in the commercially available kit (GeneTrak) and gave comparable results to standard culture methods when tested on more than 1,600 samples representing 23 food types.[108] This kit also was used to detect the DNA of *Salmonella* spp. extracted directly from filter-concentrated water samples.[196]

A second GeneTrak colorimetric kit targeted the *Salmonella* rRNA genes, which are present in multiple copies. Comparisons were made between this kit and conventional cultural and other rapid method tests based on enzyme linked-immunoassay (EIA) techniques.[69,70,286,381] D'Aoust et al.[70] also explored the use of alternative cultural conditions to improve the performance of the Gene-Trak method. Components in some selective enrichment broths appear to inhibit the gene probe assay. The probing of a combination of 6-hour Gram-negative broth postenrichment cultures inoculated from 24-hour tetrathionate brilliant green and selenite cystine enrichment enhanced the Gene-Trak assay sensitivity and specificity.

Other probes have been used for detection of *Salmonella* spp.[262,280,309,348] Wicking can separate DNA from substances that compromise DNA retention and hybridization.[309] Cells are lysed rapidly and DNA denatured using an alkali-surfactant reagent. Then, the vertical capillary action of Hybriwix filters allows DNA to migrate up the filter.

Biotin was used as the reporter molecule in a DNA probe/membrane method;[348] both dot blots from preenrichments and selective enrichments and colony blots were used. Detection of 1.6 *Salmonella* cells g^{-1} food was reported. To reduce nonspecific background, colonies should be small to allow for complete hydrolysis by proteinase K.

Salmonella virulence genes also have been used as targets. Probes to the *invA-D* genes needed for invasion of intestinal epithelial cells were used,[117] and a synthetic oligonucleotide incorporating a 1 bp difference in the plasmidborne virulence gene (*spvA*) produced a gene probe specific for *S. enteritidis*.[140]

PCR-based assays for *Salmonella* detection have used the following targets: the origin of *Salmonella* chromosome DNA replication (*oriC*),[110,373] the structural gene for thin aggregative fimbrae (*agfA*),[85] a gene for DNA binding proteins (*himA*,[23] *hns*[180]), genes for invasin proteins (*invA*, *invE*[324,325]), tyvelose-precursor synthetase—one of the genes involved in the biosynthesis of the *Salmonella* O antigens (*rfbS*),[227] *phoP*,[274] *phoE*,[198] insertion sequence 200 (IS200),[52] and other *Salmonella*-specific genetic sequences.[1,321]

Several template preparation approaches have been used for PCR-based detection. The efficiency of six different DNA extraction protocols was determined after a short cultural enrichment.[321] The most reliable, rapid, and sensitive results were obtained using Proteinase K and/or a centrifugation step to concentrate the samples. Others used guanidinium isothiocyanate following a short enrichment step,[23] or guanidinium isothiocyanate and Chelex[180] to extract DNA from oyster samples at PCR detection levels from 1–10 cells to <40 cells g^{-1} homogenized oysters. Chelex also has been used to prepare PCR template DNA from other food and environmental samples.[52,198] IMS using magnetic beads coated with six monoclonal antibodies specific for *Salmonella* serogroups A–E was an efficient way to remove and concentrate target *Salmonella* from samples such as chicken meat[110] or feces.[373]

Methods to detect PCR-amplified products from *Salmonella* include digoxigenin-labeled probes to internal sequences of the amplified products[110] and hybridization formats to "capture" amplified sequences with oligonucleotides covalently bound to microtiter wells.[52] Some applications incorporate biotin into primers[320] and both digoxigenin labeled dNTPs and biotin labeled primers.[227] Chromogenic substrates of peroxidase and alkaline phosphatase for colorimetric tests and Lumi-Phos 530 chemiluminescent substrates were compared.[320] The minimum detection levels of target DNA per microtiter plate well for chemiluminescence, peroxidase, and alkaline phosphatase methods were 1.76 fmol, 4–5 fmol, and 8–10 fmol, respectively, whereas that for agarose gel analysis was 8.8 fmol. When pure cultures were tested, initial levels of 5 cells and 50 cells could be detected by chemiluminescence and colorimetry, respectively, after amplification.

Shigella. The genus *Shigella* contains four spp: *S. dysenteriae*, *S. flexneri*, *S. boydii*, and *S. sonnei* (see Chapter 46). Genetic techniques used to detect *Shigella* spp. target both plasmid and chromosomally located virulence-associated genes. All *Shigella* spp. show greater than 80% DNA sequence similarity to *E. coli*. *Shigella* and EIEC possess similar plasmids required for virulence and this has resulted in probe and PCR methods capable of detecting both *Shigella* and some enterovirulent *E. coli* groups.

The earliest reported DNA hybridization methods used ^{32}P labeled probes to the virulence plasmid detected in *Shigella* spp. and EIEC.[37,319] Two probes were compared with the Serèny invasiveness test to characterize 42 *Shigella* and 29 *E. coli* isolates.[383] Three Serèny-test-negative isolates hybridized with both probes, suggesting that additional factors may be required for virulence. When the Boileau et al.[37] probe was applied to the direct detection of *Shigella* and EIEC in stool blots incubated overnight on MacConkey agar, the specificity for *Shigella* and EIEC remained high, but the sensitivity was poor compared with that of other cultural methods. This was attributed in part to inhibition of *Shigella* and EIEC by other fecal bacteria.[334] An alkaline phosphatase-conjugated oligonucleotide DNA probe selected from a 2.5 kb probe[319] was compared with the Serèny test by using a dot-blot format for the testing of both *Shigella* and EIEC.[269] The probe hybridized with all 52 Serèny-test-positive isolates and 4 of 21 Serèny-test-negative isolates.

Invasion plasmid antigen (*ipa*) gene probes also specifically detect *Shigella* and EIEC.[259,357,358] The *ipaH* gene, a multiple-copy element encoding a 60 kdal antigen, is located both chromosomally and on the invasion plasmid; it was selected as a target and the probe was labeled with ^{32}P[357] and suberyl-alkaline phosphatase.[259]

Other genetic elements in *Shigella* used as PCR targets include *ial* genes[90,113,161,206,390] and *ipaH* genes[162,313,314] for detection of *Shigella* spp. and EIEC. The Shiga-toxin gene and the related Shiga-like toxin gene are often used to detect *Shigella* spp. and EHEC.[164,277,278,337]

Magnetic beads coupled to monoclonal antibodies specifically captured *S. dysenteriae* and *S. flexneri* from feces, without enrichment, to prepare a PCR template for amplification of an *ial* gene fragment.[161] An alkaline phosphatase-conjugated probe was used to detect the amplified product; a minimum detection level of 10 cfu g^{-1} was achieved. When lettuce samples were tested using enrichment but without use of magnetic beads, 10^4 *S. flexneri* g^{-1} were detected.[206] The enrichment was kept short to reduce plasmid loss.

Staphylococcus aureus. *S. aureus* causes disease by formation of toxins in food (see Chapter 47). Identification of toxin type is important for epidemiological purposes.

Relying on published sequences, a set of primers was selected to detect the five types of staphylococcal enterotoxin genes and a procedure involving lysozyme, lysostaphin, and sarkosyl was used to lyse cells.[177] Using pure cultures, a sensitivity of roughly

100 toxin-producing cells was achieved when PCR products were detected by gel electrophoresis. If cells were lysed by heat treatment, positive results required at least 10^5 cells, illustrating the relative difficulty of extracting DNA from Gram-positive cells. Gene probes specific for the individual toxin types have also been developed.[168]

Staphylococci that elaborate enterotoxin type C may contaminate milk as a result of bovine mastitis. The structural genes encoding staphylococcal enterotoxins B (*entB*) and C (*entC1*) have been amplified,[378] and nested primers were used to PCR-amplify an internal segment. Primers to amplify the *entB* gene encoding type B staphylococcal enterotoxin enabled detection of about 10^5 cfu ml^{-1} of *S. aureus* seeded into milk. This sensitivity appears to be an order of magnitude or two less than in other reports,[378] suggesting PCR-inhibiting substances may have been present. With nested primers, about 1 fg per reaction of purified DNA (approximately 10 cells) could be detected. When a single set of primers was used, sensitivity was about 100 pg per reaction. Using PCR primers specific for genes for toxin types A, D, or E, detection sensitivity was about 1 cell per reaction for pure cultures and 1–10 cells g^{-1} in seeded foods after enrichment.[347] An *S. aureus*-specific gene probe to a unique region of the 16S rRNA gene was reported.[27] A nonisotopic, digoxigenin-labeled probe based on total genomic DNA was used to specifically detect *S. aureus* in meat and milk even though other staphylococci were present.[379]

***Vibrio* spp.** *V. cholerae*, *V. parahaemolyticus*, and *V. vulnificus* are the most important disease-causing members of this genus (see Chapter 48). Much nucleotide sequence information is available for virulence factors of these species. Ribotyping has also been used in epidemiology.[360] Various regions of the 16S rRNA gene are target sites for both genus-specific and species-specific gene probes and PCR primers.[87] Coelho et al.[63] constructed specific synthetic oligonucleotides for the detection of Vibrios.

The genes encoding the cholera enterotoxin (*ctxA* and *ctxB*), a major virulence factor of *V. cholerae* O1, are the targets of gene probe and PCR-based tests,[45,102,136,197,281,298,318,356,385,391] despite showing sequence similarity with the heat-labile enterotoxin gene of *E. coli* and a gene in *Salmonella*.[248,249] An oligonucleotide probe specific for a heat-stable enterotoxin produced by some strains of *V. cholerae* non-O1 (NAG-ST) showed that some *V. cholerae* O1 strains also contained this gene.[331]

Oysters, crabmeat, shrimp, and lettuce were seeded with *V. cholerae* El Tor Inaba from an ill patient, and the samples were enriched.[200] After incubation, PCR templates were prepared by boiling cultures and regions of the A and B subunit genes were amplified. Initial levels of *V. cholerae* of 10 cfu g^{-1} in oysters and 1 cfu g^{-1} in lettuce could be detected after 6 hours of enrichment.

The cytolysin gene of *V. vulnificus* has been sequenced[388] and primers selected.[152] To overcome inhibition of amplification by oyster meat, template preparation methods were evaluated. After 24 hours in enrichment medium cells were disrupted by guanidine thiocyanate and extracted with chloroform; an initial level of 10^2 cells g^{-1} oyster meat was detected. A fluorescently labeled eubacterial oligonucleotide probe to 16S rRNA genes was used to detect and enumerate *V. vulnificus* in liquid or colony hybridization formats.[142] A nonisotopic, *V. vulnificus*-specific probe to the cytolysin (*hylA*) gene could detect about 10^2 cells ml^{-1} of seawater.[386]

The majority of *V. parahaemolyticus* strains recovered from the environment lack hemolysin genes associated with virulence.[244,317] Thus, screening isolates for the hemolysin gene(s) may enable the identification of pathogenic strains; however, a family of related hemolysins complicate PCR analysis.[11,193,258,329,330] A probe for the thermostable direct hemolysin (*tdh*) gene was specific for *V. parahaemolyticus*.[213] Enzyme-labeled probes for the *tdh* gene and the TDH-related hemolysin gene (*trh*) were developed, but the *tdh* probe hybridized with some strains of *V. hollisae* and *V. mimicus*.[387] Lee and Pan [214] PCR-amplified the *tdh* gene with a sensitivity of 10^3 cells from a broth culture. A target of unknown function but specific for *V. parahaemolyticus* allowed detection, after enrichment, of 9.3 cfu g^{-1} of seeded oysters.[215]

There may be situations when all three species of *Vibrio* are sought in the same sample. Trost et al.[344] chose primer sets for the enterotoxin, the thermostable direct hemolysin, and the cytolysin genes of *V. cholerae*, *V. parahaemolyticus*, and *V. vulnificus*, respectively. These primers functioned under the same PCR conditions and generated PCR products of different sizes that could be distinguished by gel electrophoresis.

***Yersinia enterocolitica* and *Yersinia pseudotuberculosis*.** Many serotypes of *Yersinia enterocolitica* exist in nature but only a few are associated with diseases in humans (see Chapter 49). A family of 60 to 70 kbp plasmids, widely distributed in the yersiniae, is essential for pathogenicity but can be lost during growth or prolonged storage. Several chromosomal genes are required for virulence including *inv* and *ail* encoding factors for the invasion of eukaryotic cells[243] and *yst*-encoding a *Y. enterocolitica* heat-stable enterotoxin.[273]

Certain serovars of *Y. enterocolitica* are more prevalent in Europe while other groups are found more frequently in North America, although this situation is changing.[216] A set of *yst* primers differentiated between two groups of *Y. enterocolitica.*[160] Serogroup O:3 isolates recovered in Europe were characterized by a single 200-bp PCR product that matched the size predicted by the nucleotide sequence;[78] however, when serogroup O:8 strains common in North America were tested, a 1.6 kbp fragment and a 1.4 kbp fragment were observed. Such discrimination can be of epidemiological use.

A PCR-amplification of a fragment of the *ail* (attachment invasion locus) gene indicated that all 48 porcine strains and 5 clinical isolates were positive. Gene probes for *ail* in *Y. enterocolitica* and *inv* in *Y. pseudotuberculosis* are species specific.[95] Using an *inv* gene target for *Y. pseudotuberculosis*, the *ail* gene for *Y. enterocolitica*, and the *virF* primer set of Wren and Tabaqchali[384] specific for virulence plasmids found in strains of both species, Nakajima et al.[252] used PCR to differentiate between pathogenic and nonpathogenic strains. Targeting *yadA*, six pathogenic serogroups of *Y. enterocolitica* were identified with a sensitivity of 10 to 30 cfu g^{-1} of meat in the presence of a 10^6-fold excess of background microorganisms.[183] Overnight enrichment in non-selective medium increased sensitivity to about 2 cfu g^{-1} unless the number of background microorganisms was greater than 10^7 cfu g^{-1}.

Because *Y. enterocolitica* was found in the blood of asymptomatic donors, Feng et al.[97] used both a chromosomal target (*ail*) and a plasmid target (*virF*) to detect virulent strains directly in blood by using PCR. Sensitivity was 500 cfu per 100 ml of blood, but no enrichment or other method was used that would avoid possible amplification inhibitors and increase the concentration of bacteria.

It is not always clear whether plasmid or chromosomal genes should be chosen as targets; a disadvantage of the former is that loss of virulence plasmids can occur during laboratory culture.[149,151,395] In some cases both plasmid and chromosomally encoded virulence genes are required to produce disease; lack of either gene renders the cell avirulent. Because multiple primer sets can be used within the same PCR tube (multiplex PCR), it would be a reasonable strategy to test for the presence of both genes. The presence of either gene alone might indicate pathogenic potential but only strains harboring both chromosomal- and plasmid-borne genes would be considered pathogenic.

64.7.2 Viruses

Gene probes and PCR are being used to test for foodborne viruses and can detect fewer than 10 virus particles. RNA-genome viruses can be detected by the use of RT to form cDNA that serves as a PCR template.

Norwalk Virus. This virus is probably the leading cause of non-bacterial gastroenteritis among adults in the US (see Chapter 52) and cannot be grown in cell culture. RT coupled PCR (RT-PCR) can detect Norwalk virus in stools[173] and in shellfish.[394] Extraction of viral RNA from oysters by homogenization, organic flocculation, and polyethylene glycol[9] resulted in a PCR sensitivity of about 50 to 500 seeded Norwalk virus particles per gram of oyster compared with 1.5 to 15 particles per reaction from seeded stool samples. After Norwalk virus was seeded into shellfish, genomes were recovered by treatment with guanidinium isothiocyanate and hydroxyapatite followed by cetyltrimethylammonium bromide and ethanol precipitation.[131] Primers targeted to the RNA polymerase gene allowed detection of 20 to 200 molecules of Norwalk virus RNA per reaction. Similar results were obtained for Norwalk-like viruses (small round-structured viruses, SRSV) seeded into oysters and mussels as well as in shellfish implicated in human gastroenteritis.[218]

An outbreak on a cruise ship allowed the comparison of PCR detection and identification with serological techniques.[189] Of 19 fecal specimens examined, 7, 19, and 5 were positive by electron microscopy, PCR, and immunoassay, respectively. The PCR-amplified region shared only 81% homology with that of a reference strain, suggesting an explanation for the low detection rate by enzyme-linked immunosorbent assay (ELISA).

Fresh-cut fruit was implicated as the carrier of Norwalk virus in an outbreak on a cruise ship. Of 10 fecal specimens assayed, 4 were positive by RT-PCR and the nucleotide sequence of the amplified product helped to identify the viral strain.[146] Consumption of contaminated oysters was suspected in a multistate outbreak; 20 of 26 (77%) samples were positive by RT-PCR.[88] Antigenically distinct SRSVs have been differentiated by using RT-PCR, taking advantage of nucleotide sequence differences.[8] Fecal samples from 19 outbreaks were examined by RT-PCR; 64%, 40%, and 8% of the samples were positive from outbreaks involving Norwalk virus, Norwalk-related viruses, or SRSV, respectively.[8]

To increase the sensitivity of PCR for Norwalk virus detection, De Leon et al.[77] used an RT-PCR-OP (oligoprobe). After removing RT-PCR inhibitors in fecal specimens by Sephadex G-200 gel chromatography, two sets of primers amplified regions of the RNA polymerase gene and a putative antigenic protein. Amplification products were detected with a digoxigenin-labeled oligonucleotide. A stool sample contained about 10^6 virions ml^{-1} as determined by immunoelectron microscopy and after a 10^4-fold dilution 10 μl still gave a positive amplification; therefore, the sensitivity of this method was close to one virion.

Rotavirus. Serotype-specific cDNA molecules were generated as gene probes to detect rotaviruses of porcine origin.[287] Gouvea et al.[130] targeted the major outer capsid glycoprotein gene (vp7) to detect rotavirus in fecal samples from humans with a sensitivity of about 2 ng (equivalent to 10^8 viral genomes). A PCR typing method was developed where each serotype resulted in a fragment of a characteristic size. Purification of templates by binding rotaviral RNA to a CF11 cellulose column in buffered ethanol increased sensitivity more than 1000-fold, presumably through the removal of PCR inhibitors.[375]

***Hepatitis A Virus* (HAV).** A number of seafoods (such as oysters) are consumed raw and, if grown in contaminated waters, can spread HAV to humans;[81] HAV can survive for up to several months in experimentally contaminated environments. HAV is easily transmitted by the fecal-oral route, and the period of communicability precedes the onset of clinical symptoms; thus rapid detection is essential for containing the spread of disease.

Jansen et al.[166] selectively captured virus particles in fecal samples by using anti-HAV monoclonal antibodies, released viral RNA by heating, and amplified it by RT-PCR. Sensitivity was 3 to 30 virus particles per reaction; Southern blot analysis of PCR products yielded a detection rate of 90%, whereas solid-phase radioimmunoassay and cDNA-RNA hybridization resulted in 50% and 65% positive samples, respectively. Use of antigen capture and RT-PCR to test seeded oysters and detection of PCR products with gene probes gave a sensitivity of about 4 virus particles per reaction.[80] Atmar et al.[9] attempted to detect HAV in seeded oysters by using a sample preparation method developed for Norwalk virus. Using a RT-PCR method, HAV could not be detected in seeded oysters but was detected if the virus was added to extracts of oysters. It was found that HAV was removed from the supernatant during the flocculation step. This finding illustrates the difficulty in extrapolating methods from one microbe and sample type to others. When RNA isolated from clams was used in RT-PCR,[129] 10 viral RNA molecules were detected in seeded samples. By using riboprobes, 67% of shellfish examined were found to contain HAV RNA.[219] There was no correlation between viral contamination and fecal coliform counts.

Enteroviruses. These RNA-containing viruses are a diverse group of pathogens and a common cause of childhood infections, the most notable of which is polio (see Chapter 52). It is difficult to detect these viruses with gene probes because titers of virus in clinical samples are usually low. Because the complete nucleotide sequences for several enteroviruses have been determined, RT-PCR methods have been applied.[288] A conserved region at the 5' end of the enteroviral genome was targeted. Assay sensitivity was in the range of 10^6 molecules per reaction; more importantly, the time required to detect and identify these viruses was shortened from 4 to 8 days by tissue culture to less than 1 day.

Using poliovirus seeded into oysters as a test system, Atmar et al.[9] found that flocculation and polyethylene glycol precipitation left RT-PCR inhibitors in the extracts but that they could be removed by CTAB (cetyltrimethylammonium bromide) allowing detection of 10 plaque-forming units. Similar results were reported by Lees et al.[217] Positively charged nylon membranes were used to capture enteroviruses from water samples, and RNA was isolated with oligonucleotides bound to magnetic beads.[125] The detection limit was 20 times the amount required to infect 50% of tissue culture cells (equivalent to about 1,000 virions in an original volume of 1 l). Of 40 water samples tested, 7 (17%) were positive.

64.7.3 Parasites

Cryptosporidium. Target genes for PCR include the 18S rRNA gene,[10,175] the 5' end of 18S and 5.8S rRNA genes,[47] and other *Cryptosporidium*-specific genes.[61,103,211] The sensitivity of PCR analyses was reduced up to 1000-fold when water samples were used instead of pure cultures. The use of flow cytometry or IMS separated *Cryptosporidium* from PCR-inhibiting substances.[175] Detection of PCR-amplified products with chemiluminescently labeled oligonucleotide probes also improved the PCR sensitivity 10 to 1000-fold.[175]

Entamoeba. DNA probes to rRNA can detect *E. histolytica;*[305] other probes distinguish between pathogenic and nonpathogenic isolates.[120,333] A PCR assay amplifies genetic sequences specific for *E. histolytica.*[332] Unique RFLP patterns for PCR-amplified product allowed pathogenic and nonpathogenic isolates to be distinguished.[332]

Giardia. *Giardia duodenalis* is the most frequently identified cause of waterborne intestinal disease in the US; *G. lambia* also is isolated from humans. Disruption of *Giardia* cysts with glass beads and Proteinase K was the most efficient protocol for extracting nucleic acids prior to DNA probe hybridization specific for the small rRNA subunit.[2] The giardin gene of *Giardia* has been identified as a target for the selection of PCR primers and internal probes for the detection either of *Giardia* cysts or to discriminate between *Giardia duodenalis* and other *Giardia* spp.[231,232]

64.8 TYPING OF FOODBORNE MICROBES

64.8.1 Introduction

DNA subtyping can be used in studies of the epidemiology of foodborne disease. In many reports, the analysis of DNA subtyping patterns of bacteria has been limited to visual inspection and manual classification into groups; however, similarity values between nucleotide sequences or gel patterns from isolates can be used to generate clusters. Dendrograms (ie, tree diagrams) can be used to visualize and sometimes to quantify the relationships between strains of a given bacterial species. Other pattern analysis and visualization techniques, such as principal coordinate analysis (PCoA), can be used to explore groupings of subtyping data. By using these methods, a new isolate can be compared with a database of previously classified isolates to designate the most similar ones. Each phenotype-based subtyping method such as serotyping, phage typing, and biotyping has its associated advantages and disadvantages, such as the number of groups generated and the problem of untypeable strains. DNA subtyping methods, although sometimes labor-intensive, have some advantages, and generally use commercially available reagents, rather than specialized materials such as specific antisera or collections of typing phages.

In general, DNA subtyping methods fragment genomic DNA to generate a pattern of fragment sizes or a nucleotide sequence (which is also a pattern). The most commonly used subtyping methods for characterizing bacterial genomes are PFGE,[34] ribotyping,[32] random amplified polymorphic DNA (RAPD),[367] or DNA sequencing.[264]

64.8.2 Restriction Fragment Length Polymorphism (RFLP)-Based Methods

Pulsed-Field Gel Electrophoresis (PFGE). Restriction enzymes that cut DNA infrequently are used to generate a low number (about 20 to 30) of fragments.[236] Most of these fragments are quite large (approximately 10 to 1,000 kbp) and need special electrophoretic separation methods.[34] The resulting fragment patterns represent the position of cleavage sites for a particular restriction enzyme and are used to group isolates.[127] Guidelines for bacterial subtyping by using PFGE DNA restriction fragment patterns have been published.[336]

Ribotyping. This reveals the distance between restriction enzyme sites on DNA fragments encoding genes for ribosomal RNA molecules. The restriction enzymes cleave DNA molecules to produce between about 500 and 1,000 fragments with an average size of about 1 to 20 kbp, which are separated by gel electrophoresis. Because this number of bands cannot be resolved readily, bands containing ribosomal sequences only are detected by hybridization with a probe encoding *E. coli* ribosomal RNA genes. These simplified patterns are used to discriminate between strains.[133,199]

PCR/RFLP. Restriction enzyme analysis of PCR-amplified DNA can be a rapid and powerful tool for discriminating between strains. For example, the 16S-23S rDNA spacer regions in *Staphylococcus aureus* were analyzed in this way.[137] Clear differences were observed between *C. perfringens* and *C. botulinum* and between *C. botulinum* neurotoxin types C and G.[138]

64.8.3 Random Amplified Polymorphic DNA

In the standard PCR, specific oligonucleotide primers are used to generate a segment that usually does not vary between isolates. In contrast the DNA produced by the RAPD method results in patterns that can be used to compare strains. These patterns arise from using a single, short primer (about 10 nucleotides) with reaction conditions that allow mispairing of primer and template DNA; thus, the primer will anneal at many different places throughout the genome. Randomly, some primers will be

Next Page

positioned such that amplification can occur in conjunction with other nearby primers. A number of regions will be amplified that are bounded by nucleotide sequences showing similarity to the primers. Because bacteria have different nucleotide sequences, they may exhibit distinguishable patterns. Although this technique appears to be difficult to conduct reproducibly (probably because of variations in template concentration and thermocycling), it is of interest because of its relative simplicity and speed.[126,271] RAPD analysis has been used to discriminate between strains of *E. coli*,[54] *Y. enterocolitica*,[283] *V. vulnificus*,[264] and *Salmonella enteritidis*.[299] In some cases, RAPD can distinguish strains that appear identical by multilocus enzyme electrophoresis.[363]

64.8.4 DNA Sequencing

Perhaps the eventual limit on the description of an organism will be the nucleotide sequence of its genome. Without requiring these data for the entire genome, it is possible to make taxonomic assignments by sequencing some regions of the genome that are variable between species but conserved within species, eg, the genes for the ribosomal RNAs. Nucleotide sequences of 16S rRNA genes from several species of foodborne pathogenic bacteria were retrieved from the GenBank® database[82] or the Ribosomal Database Project,[209] and aligned to generate a similarity matrix. By using hierarchical cluster analysis,[242] these sequences were grouped according to their similarity, which closely reflected their taxonomic position.[153] Gel banding patterns can be treated in a similar fashion but additional care must be taken to consider the variation in band peak position.[275]

PCR can be used in conjunction with sequencing to analyze bacterial colonies. One PCR adaptation employs unequal concentrations of primers so that one product strand will predominate and be available for sequencing.[139]

64.8.5 Examples Using *Vibrio cholerae*

Prompted by an epidemic in Latin America, the body of evidence on the molecular genetic epidemiology of *V. cholerae* based on several techniques is increasing rapidly. Olsvik et al.[264] developed a streamlined sequencing protocol based on PCR-amplified *ctxB* DNA to assist the rapid collection of this type of subtyping data. Based on the RFLP analysis of rRNA and *ctxA* genes, DNA sequences of the *ctxB* gene, PFGE, and multiple locus enzyme electrophoresis (MEE), Wachsmuth et al.[361,362] concluded that the Latin American clone of *V. cholerae* is closely related to the seventh pandemic strain. Similarly, the nucleotide sequence of the *ctxB* gene of *V. cholerae* O139, the strain responsible for outbreaks throughout Southeast Asia, resembles that of the classical biotype more than that of El Tor strains.[212] The RAPD fingerprinting method was applied to O139 strains, and the resulting patterns indicate that they comprise a unique subgroup genetically distinct from O1 strains and possibly arising from the El Tor biotype.[28,233] Similar DNA subtyping data were obtained using PCR, ribotyping, and PFGE on recently isolated strains from patients, food, and the environment.[352]

64.9 CONCLUDING REMARKS

The use of gene probes and the PCR has increased dramatically within the past few years, and a considerable number of variations on these basic techniques have been devised. Although most of the applications of these methods have been for clinical and environmental samples, the use of these methods to detect pathogenic microorganisms in foods is increasing. Virtually every important foodborne pathogenic bacterial species has been studied and gene probes and PCR primer sets developed for their detection and identification. Both virulence genes, to detect pathogenic strains, and rRNA genes, to detect particular taxonomic groups, are being used as probes and/or PCR targets. A considerable amount of effort is being expended to develop efficient and rapid protocols for the preparation of target DNAs from complex food matrices and, in some cases, considerable progress has been made. These methods, along with ribotyping, PFGE, and random amplified polymorphic DNA, also have been used to subtype strains and generate important epidemiological information for analyzing outbreaks of foodborne disease.

65.1 INTRODUCTION

Since microorganisms were first recognized by man to cause foodborne illness and to spoil foods, microbiologists have been concerned with assessing the microbiological risks associated with foodstuffs and identifying means for their reduction, management, and control.

In the early part of the 20th century, safety concerns led to the development of performance criteria for thermally processed foods based on an estimation of the microbial kill needed to produce a safe food. The best known examples of these are the "Botulinum Cook," a thermal process designed to reduce the probability of survival of spores of *Clostridium botulinum* by a factor of 10^{12} and pasteurization, introduced to reduce the numbers of infectious pathogenic microorganisms present in raw milk to safe levels (see Chapter 3).

Similar concerns over salmonellas and other infectious and toxigenic microorganisms in raw and processed foods led to the development of microbiological criteria. These are used to assess whether an amount of food contains a concentration of a microorganism or a microbial toxin in excess of that regarded as acceptable. The first of such criteria had little scientific basis and Sedwick, referring to the basis of many microbiological standards, stated, "Standards are often the quote of one worker, easily seized upon, and quoted and requoted until they assume a semblance of authority."[64]

It was not until the early 1970s that microbiological criteria were placed on a sound basis by the International Commission on Microbiological Specifications for Foods (ICMSF).[35] The ICMSF introduced the use of statistically based sampling plans as part of a microbiological criterion and based the stringency of such plans on a consideration of three elements of hazard and risk. First, the degree of severity and extent of illness potentially caused by a microorganism or toxin contaminating a food. Second, the relative sensitivity of the intended consumer of the food to infection or intoxication by the food. Third, the likely fate of the microorganism (or toxin) between when the food is sampled and when it is consumed (ie, would it survive, increase, or be destroyed during any subsequent manufacturing process, during distribution, and/or preparation for use?). Based on these factors, the ICMSF proposed a matrix of 15 sampling plans (Table 65–1).[35] This matrix is used throughout the world by regulatory authorities and by industry for the establishment of microbiological criteria for foods.

Methods of microbiological risk assessment (MRA) and hazard analysis are of increasing interest to governments and the food industry. There are a number of reasons for this, including the potential cost/benefits to regulatory authorities of using risk assessments to prioritize public health concerns and allocating health resources accordingly,[1] the use by industry of hazard analysis, as part of Hazard Analysis and Critical Control Point (HACCP), to identify and to analyze microbiological and other hazards as-

Table 65–1 ICMSF Matrix of Stringency of Sampling Plan in Relation to Hazard and Conditions of Handling and Use*

	Conditions in Which the Food Is Expected To Be Handled and Consumed after Sampling		
Type of Hazard	*Reduced Concern*†	*No Change*††	*Increased Concern*§
No direct health hazard (eg, shelf life/spoilage)	Case 1 n = 5, c = 3	Case 2 n = 5, c = 2	Case 3 n = 5, c = 1
Health Hazard:			
Low indirect (indicator organisms) (eg, coliforms)	Case 4 n = 5, c = 3	Case 5 n = 5, c = 2	Case 6 n = 5, c = 1
Moderate direct (limited spread) (eg, *S. aureus, B. cereus)*	Case 7 n = 5, c = 2	Case 8 n = 5, c = 1	Case 9 n = 10, c = 1
Moderate direct (potentially extensive spread) (eg, *salmonella*, *shigella*)	Case 10 n = 5, c =0	Case 11 n = 10, c = 0	Case 12 n = 20, c = 0
Severe direct hazard (eg, *E. coli* 0157:H7; *S. typhi*)	Case 13 n = 15, c = 0	Case 14 n = 30, c = 0	Case 15 n = 60, c = 0

* Cases 1–9 are Three-Class Plans; cases 10–15 are Two-Class Plans; n = number of sample units tested; c = maximum allowable number of defective sample units (Two-Class Plans) or marginally acceptable sample units (Three-Class Plans). (For further information see Section 65.3.3.3).

† Reduced concern: eg, frozen raw crustacea cooked before consumption;†† No change: eg, chocolate;§ increased concern: eg, chill-stored, cooked meat products.

sociated with a particular food operation, and to design-in appropriate control measures (see Chapter 58).

A further need for formal MRA procedures arises from the recently implemented World Trade Organization Agreement on Sanitary and Phytosanitary Measures.[3] This requires a member government to base its laws for protecting human, animal, and plant health on an assessment of the risks involved and to be able to demonstrate that its national requirements are no more restrictive to trade than those required to protect the health needs of its subjects.

The Codex Alimentarius Commission's "Principles for the Establishment and Application of Microbiological Criteria for Foods" states that, "Microbiological criteria should be established according to these principles and be based on scientific analysis and advice, and where sufficient data are available, a risk analysis appropriate to the foodstuff and its use."[18,25] As Codex is recognized in the Sanitary or Phytosanitary (SPS) Agreement as the main source of international consensus on requirements for the production and distribution of safe foods, the principles for establishing microbiological criteria and any criteria derived from these would be expected to be accepted internationally. Additional information on the use of risk assessment as a foundation for establishing effective science-based food safety management systems is available.[14,37,38,53]

This chapter considers the developing links between microbiological risk assessment and microbiological criteria and reviews some of the options for objectively assessing microbiological risks and the use of microbiological criteria as one of the means of managing such risks.

65.2 RISK ASSESSMENT

65.2.1 Background

Risk assessment has been described as the process of organizing information concerning a particular risk in a systematic way so that decision makers can better understand those factors that contribute to the risk and any uncertainties that may affect the outcome of an assessment.[49]

The process of microbiological risk assessment has not progressed as far, or as fast, as other public health-oriented risk assessment procedures. The reasons why this process has proved more difficult than other such risk assessments include the inherent variability in virulence and growth characteristics of individual strains of specific microbial pathogens; their likely change in numbers in a food as it moves along the food supply chain; the often specific effects of foods and food components on virulence and survival of microorganisms through the intestinal tract;[4] and the idiosyncratic nature of the human response to infection.[1,9,23]

Microbiological risks associated with the consumption of food depend on the numbers, types, and virulence of organisms present in a food (or amounts of a microbially produced toxin or metabolite) at the time of consumption and the susceptibility of the person consuming the food to infection or intoxication by these. Thus any MRA must take account of microbiological knowledge concerning the likely occurrence and fate of microorganisms in a foodstuff, the possible influence of the food or the production process on the virulence, or survival of such organisms and/or their toxins, together with medical knowledge concerning the number of microorganisms or the amount of toxin estimated to cause illness, and the seriousness of such illness in terms of morbidity and mortality.[6]

The process of MRA generally involves four phases. The first is definition of the scope of the assessment (problem definition stage). The second involves collecting and organizing available relevant data and identifying important areas where data are absent (data collection and collation stage). The third involves analysis of the problem (problem analysis phase), a phase that will involve the use of some systematic process of risk assessment. In the fourth phase all the information is brought together to give an estimate of the probability of the occurrence of an adverse health effect (risk characterization phase).

Potential approaches to MRA include structured risk assessment techniques used in other disciplines. These include such techniques as Hazard and Operability Studies, Fault Tree Analysis, and Event Tree Analysis, these being used mainly for the evaluation of risks associated with chemical and physical hazards, including explosion risks and engineering failures associated with particular types of production plant.[1,40]

Further methodologies include Probabilistic Scenario Analysis[13] and the use of the paradigm used in formal and structured risk assessments of food ingredients, additives, and chemical contaminants based on a four-step procedure of Hazard Identification, Hazard Characterization, Exposure Assessment, and Risk Characterization.[15,23,63] The use of this latter procedure for MRA is being studied by a number of governmental bodies around the world (including the Codex Alimentarius Commission) with particular emphasis on attempting to use it to establish quantitative, or at least semiquantitative, risk assessment procedures.[24,32,63,71]

A drafting group of the Codex Committee on Food Hygiene met in 1996 and drafted a series of principles for applying MRA.[24] The following is based on the development of these principles by a working group of the European Union's Scientific Committee for Foods.[63]

- **Risk assessment must be soundly based on science**. Where scientific data are limited, otherwise incomplete, or conflicting, informed judgments should be made on the basis of the best available information.
- **Risk assessment should be separated functionally from risk management**. The latter is a separate process that is consequential on risk assessment and aimed at identifying options for action needed to manage an unacceptable risk and has a policy function.
- **A structured approach must be used when conducting a risk assessment of a microbiological hazard**. This structured approach should include Hazard Identification, Hazard Characterization, Exposure Assessment, and Risk Characterization; the order in which these steps are applied will depend on the assessment undertaken.
- **A risk assessment of a microbiological hazard must clearly state both the purpose of the assessment and the form of the risk estimate that will be the output**. The purpose may be, for example, to estimate the risk of a microbiological hazard in the total food supply or the microbiological hazards associated with a specific commodity. The output may be an estimate of the annual rate of illness in a population or the rate of illness per eating experience, etc.
- **The risk assessment must be transparent**. It must be fully documented, including any con-

straints that may have affected the quality of the risk estimate, and be freely available to independent assessors.

- **The risk estimate must contain a detailed description of uncertainty and where this arose during the Risk Assessment Process.**
- **The data used in a risk assessment must be of sufficient quality and precision that uncertainty in the risk estimate is minimized as far as possible.** Quantitative data should be used to the extent possible.
- **Where appropriate, a risk assessment of a microbiological hazard must consider the fate of the hazard(s) in food(s) and the disease process following infection.** It should consider the dynamics of microbial growth, survival, and death, and, where applicable, the dynamics of microbial toxin formation and destruction, together with distribution of the agent in the foodstuff(s) and interactions between the agent and the human body following consumption (including sequelae and the potential for secondary spread).
- **Risk estimates, where possible, must be reevaluated over time against human health data and when new data become available.**

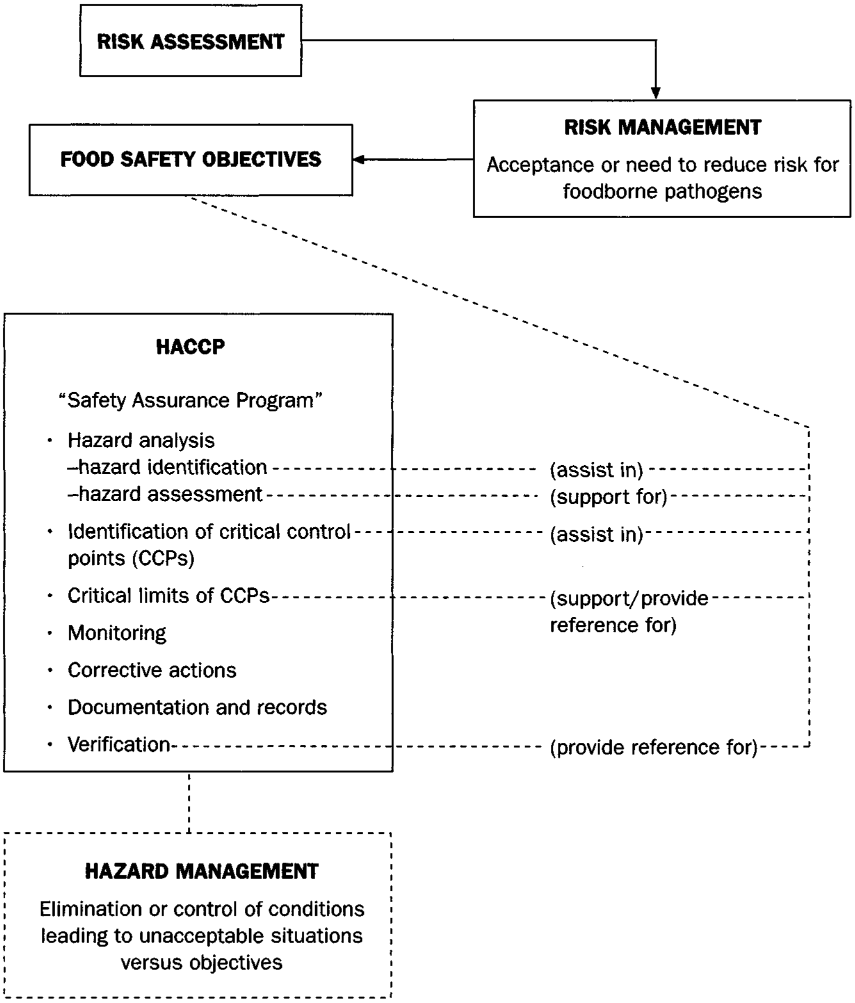
A potential problem that has emerged during the initial attempts to develop a MRA process has been the confusion caused by the partial or total inclusion of the MRA procedure, as under development by Codex, into HACCP in an attempt to make the latter more quantitative.[13,55] While elements of HACCP include a risk estimate, it is important that the two processes are kept separate for the following reasons.

1. MRA, as defined by Codex, is a government-led procedure to be used by a regulatory authority to assess whether a particular microbiological hazard is an unacceptable health risk to a population, whereas HACCP is an industry-led procedure to be used by industry to identify and control the specific microbiological hazards associated with the production of a specific food or food ingredient using a specified procedure. These two separate processes are linked, as shown in Figure 65–1.
2. HACCP is based on a hazard analysis procedure leading to options for control based on hazard management (see Chapter 58), whereas risk assessment leads to the identification of control options based on risk management.[22]
3. The knowledge base and expertise needs of those involved in HACCP and MRA are quite different. Thus, factory personnel, microbiologists, and hygiene specialists would be involved in the development of a HACCP plan, whereas specialists with in-depth knowledge of a microbiological hazard, such as basic scientists, epidemiologists, and public health specialists would be involved principally in MRA. These latter specialists are unlikely to have the experience or knowledge to correctly identify the hazards and their control requirements in the many and varied food operations that exist throughout the food chain. Factory personnel, factory microbiologists, and hygiene specialists are unlikely to have the depth of knowledge concerning the biology of a pathogenic microorganism, and its role in foodborne disease, to properly estimate its risk as a contaminant in the human food chain.
4. To confuse the processes of risk assessment and HACCP would be prejudicial to their proper development, recognizing that they are distinct but interrelated procedures (Figure 65–1) for sound reasons (see Chapter 58).[66]
5. A HACCP team in a factory may use a published MRA as a source of information when conducting a hazard analysis of a food production operation. Those conducting an MRA, however, would not use the hazard analysis from HACCP plans as a resource material.

65.2.2 Definitions

Before further considering risk assessment procedures and their potential use in microbiological risk assessment, it is important to define some of the key words and phrases that are used because some of these differ from their common and expected usage.

When considering definitions, one is faced with a wide selection of possibilities, which is a reflection of the early state of development of this evolving branch of quantitative microbiology. One of the most recent attempts to establish an internationally accepted set of definitions was by a Joint Food and Agriculture Organization of the United Nations/World Health Organization (FAO/WHO) Expert Consultation on the "Application of Risk Analysis to Food Standard Issues."[23] These definitions were later modified by the Codex Alimentarius Commission[21] and, although they are likely to be subject to further revision before becoming finally internationally accepted, they currently form a consensus of international opinion. They are used in the following



RISK ASSESSMENT
RISK MANAGEMENT
Acceptance or need to reduce risk for foodborne pathogens
FOOD SAFETY OBJECTIVES
HACCP
"Safety Assurance Program"
• Hazard analysis
–hazard identification
–hazard assessment
• Identification of critical control points (CCPs)
• Critical limits of CCPs
• Monitoring
• Corrective actions
• Documentation and records
• Verification

paragraphs as the basis for discussion and are summarized in Exhibit 65–1.

Hazard. "A biological, chemical or physical agent in, or condition of, food with the **potential** to cause an adverse health effect."[21]

In most definitions, a microbiological hazard is defined simply as an inherent danger associated with a particular organism or toxin. In some sources, this simple definition is extended to include that to be a significant health concern, a certain number of organisms or an amount of a microbial toxin must be present. Thus the ICMSF[25] describes a microbiological hazard as **unacceptable** growth, survival, or contamination of a food with microorganisms and/or unacceptable production or persistence in foods of products of microbial metabolism such as toxins, enzymes, and biogenic amines. The International Life Sciences Institute Monograph on HACCP[39] combines the Codex definition with the ICMSF definition and states, "In the HACCP framework the term hazard refers to any agent in, or condition of, a food that is unacceptable because it has the potential to cause an adverse health effect." Here "condition" as in the Codex definition appears to refer to a condition arising as a result of contamination such as spoiled, adulterated, or unwholesome food, but this would seem to confuse the definition of a hazard. A recently completed document on HACCP by the US National Advisory Committee on Microbiological Criteria for Foods[51] defines a hazard as a "biological, chemical or physical agent that is reasonably likely to cause illness or injury in the absence of its control."

Exhibit 65–1 Definitions of Terms Applied to Risk Assessment and Hazard Analysis

Hazard: A biological, chemical, or physical agent in, or condition of, food with the potential to cause an adverse health effect.

Hazard analysis: The process of collecting and evaluating information on hazards, and conditions leading to their presence, to decide which are significant for food safety and therefore should be addressed in an HACCP plan.

Risk: A function of the probability of an adverse health effect and the severity of that effect consequential to a hazard(s) in food.

Risk assessment: A scientifically based process consisting of hazard identification, hazard characterization, exposure assessment, and risk characterization.

Hazard identification: The identification of biological, chemical, or physical agents capable of causing adverse health effects and that may be present in a particular food or group of foods.

Hazard characterization: The qualitative and/or quantitative evaluation of the nature of the adverse health effects associated with biological, chemical, and physical agents that may be present in food. For chemical agents, a dose-response assessment should be performed. For biological or physical agents, a dose-response assessment should be performed if the data are obtainable.

Dose-response assessment: The determination of the relationship between the magnitude of exposure (dose) to a chemical, biological, or physical agent and the severity and/or frequency of associated adverse health effects (response).

Exposure assessment: The qualitative and/or quantitative evaluation of the likely intake of biological, chemical, or physical agents via foods as well as exposure from other sources if relevant.

Risk characterization: The qualitative and/or quantitative estimation, including attendant uncertainties, or probability of occurrence and severity of known or potential adverse health effects in a given population based on hazard identification, hazard characterization, and exposure assessment.

Risk management: The process of weighing policy alternatives in the light of the results of risk assessment and, if required, selecting and implementing appropriate control options, including regulatory measures.

Risk communication: The interactive exchange of information and opinions concerning risk among risk assessors, risk managers, consumers, and other interested parties.

Infection: Successful colonization of the host by a microorganism capable of causing damage to its host.

Risk. "A function of the probability of an adverse health effect and the severity of that effect, consequential to a hazard(s) in food."[21]

Severity is considered to be a component of risk by toxicologists and others;[49] however, most microbiologists also would consider severity as a component of a microbiological hazard. Thus, the presence of *C. botulinum* in an ambient-stable, low-acid canned food is a severe hazard but if the thermal process and other control measures are properly applied, the probability of this occurring is very, very low; therefore, the risk (ie, the likelihood) of botulism is extremely low. As a health concern must always take account of both seriousness and probability of occurrence, the overall conclusion as to whether or not there is a significant health concern does not change if severity is linked with risk rather than hazard. However, we believe that this is confusing and prefer to relate severity to hazard rather than to risk.

Risk Assessment. "A scientifically-based process consisting of the following steps: (1) Hazard Identification; (2) Hazard Characterization; (3) Exposure Assessment; (4) Risk Characterization."[21]

In outline it is a structured and formal procedure for identifying and characterizing a hazard and estimating (ie, quantifying) the effects of that hazard on a population.

> ***Hazard Identification.*** The identification of biological, chemical, and physical agents capable of causing adverse health affects and which may be present in a particular food or group of foods.

Hazard identification would include known hazards, such as those identified as a result of epidemiological studies of foodborne disease incidents, and potential hazards, such as those identified by research studies into the survival/growth characteristics of a pathogen in a foodstuff (see Section 65.2.3.1).

> ***Hazard Characterization.*** The qualitative and/or quantitative evaluation of the nature of the adverse effects associated with biological, chemical, and physical agents which may be present in food. For chemical agents, a dose-response assessment should be performed. For biological or physical agents, a dose-response assessment should be performed if the data are obtainable.

Hazard characterization provides an estimate of the severity and extent of illness likely to be caused by a particular number of microorganisms or an amount of a microbial toxin. The availability of soundly based dose response data is a particularly problematic part of hazard characterization because of the large number of factors that can affect this determination. Ideally, quantitative estimates are developed for the probability of an adverse health effect relative to the amount of agent consumed. This is discussed in detail in Section 65.2.3.2.

> ***Exposure Assessment.*** The qualitative and/or quantitative evaluation of the likely intake of biological, chemical, and physical agents via foods as well as exposures from other sources if relevant.

Obtaining meaningful microbiological data of numbers of a pathogen present in a food at the point of consumption is a difficult task because of the variable occurrence of pathogens in foods and the environment and large effect that processing, distribution, and preparation procedures for consumption can have on these numbers (see Section 65.2.3.3).

> ***Risk Characterization.*** The qualitative and/or quantitative estimation, including attendant uncertainties, of the probability of occurrence and severity of known or potential adverse health effects in a given population based on hazard identification, hazard characterization, and exposure assessment.

This is the final step in the risk assessment procedure where the information obtained in the three previous steps is brought together into a statement of an estimate of microbiological risk(s) to a given population.

Risk Analysis. "A process consisting of three components: Risk Assessment, Risk Management and Risk Communication."[21,23]

It is important that the relationship between ***Risk Assessment***, ***Risk Management***, and ***Risk Communication*** is understood. ***Risk Assessment*** is the four-step procedure described above and results in a risk estimate. ***Risk Management*** is the separate process of weighing policy alternatives in light of the results of risk assessment and selecting and recommending control options if the risk needs to be controlled. It consists of the processes of Risk Evaluation, Risk Management Option Assessment, Implementation of Management Decisions, and Monitoring and Review.[22] ***Risk Communication*** is the exchange of information and opinion interactively among risk assessors, risk managers, and other interested parties. These two latter activities are outside the scope of this chapter, but the use of a microbiological criterion, which will be considered later, is an example of the application of a Risk Management option. Also, any regulation or guideline that incorporates such a microbiological criterion would be a form of risk communication. The interrelationship between Risk Assessment, Risk Management, and Risk Communication is shown in Figure 65–2.

Hazard Analysis. "The process of collecting and evaluating information on hazards, and conditions leading to their presence, to decide which are significant for food safety and, therefore, should be addressed in the HACCP plan."[25]

It is particularly important to recognize the specific use of the words hazard, risk, risk assessment, risk analysis, and hazard analysis in the following sections on microbiological risk assessment and microbiological criteria.

65.2.3 Status and Application

The following section reviews the status of the basic knowledge needed for a microbiological risk assessment and examples of its application. It will consider this knowledge base against the needs of the four-step risk assessment process described above and it will attempt to identify what new information will be needed to make this type of risk assessment possible.

65.2.3.1 Hazard Identification

Knowledge of microbiological hazards is derived mainly from accounts of epidemiological investiga-

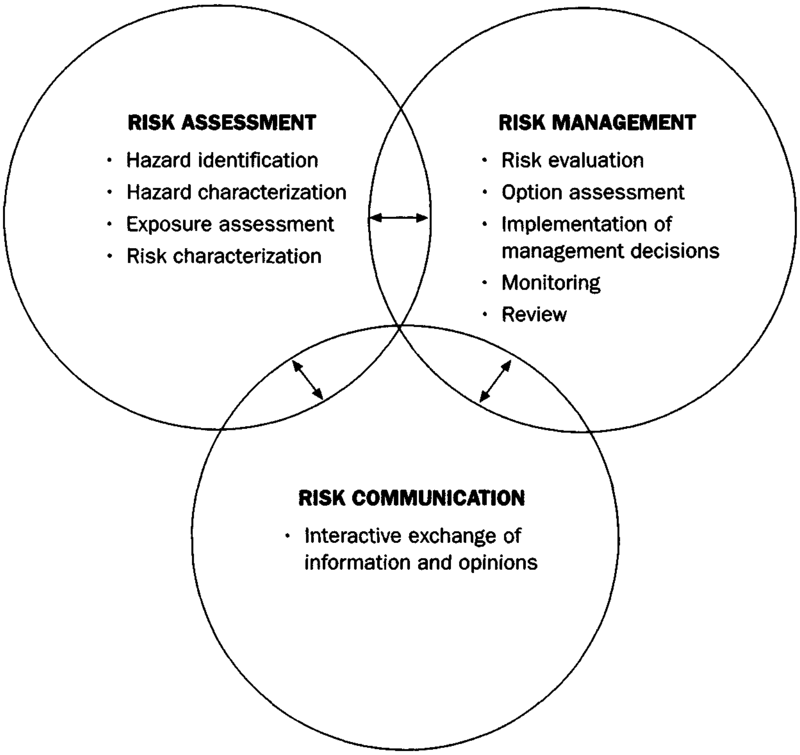

Figure 65–2 Risk Analysis Framework. *Source:* Adapted with permission from SCF, *Principles for the Development of Risk Assessment of Microbiological Hazards for the Development of Hygiene Risks for Food Stuffs as Covered by the Hygiene of Foodstuffs Directive 93/43/EEC.* Scientific Committee for Foods (SCF) DG 24, © 1997, European Commission, Brussels.

tions and records of incidents of foodborne illness. Additional information may be derived from clinical studies. The uses and means of obtaining epidemiological and clinical information are described in Chapter 37, together with the limitations of such information. Briefly, our knowledge of the extent and many of the causes of foodborne illness is very incomplete as there is gross underreporting of such illness in all countries. Even when there is a report of an illness with symptoms that suggest that it may be foodborne, the cause of the illness is often unknown and the food involved seldom identified.[7,8,59,69,78]

The reasons for underreporting, in addition to the often lack of an effective reporting scheme, include failure of an ill person to seek medical help, failure of the clinician to report a case of suspected foodborne illness, absence of suitable samples for analysis, and the cost and difficulties involved in investigating an incident. Cost is particularly a constraint when an incident may involve only one or two cases of a distressing, but not life-threatening, illness. Thus, only incidents involving multiple cases (ie, outbreaks) are investigated in sufficient depth to provide data that can be used for hazard identification. Such data should include causative agent (amount or number involved); source of agent and circumstances that lead to it causing illness; type(s) of foods involved; extent of illness and persons involved (age, health status); and type of illness caused including time from consumption, symptoms, severity, and duration.

Additional factors that may influence the identification of a new etiological agent of foodborne illness include the availability of detection methods and the effect of incubation time. In the former, a number of years usually will elapse between identification of a new agent and the development of reliable and sensitive methods of detection. In the latter, acute illness with a short incubation time among a group of people eating a common meal would be more likely to be recognized as an outbreak than if the symptoms required days for onset and the participants in the meal are widely dispersed. Microorganisms causing outbreaks always will be more recognized as a health concern than those only causing sporadic cases. This can be illustrated by the fact that listeriosis only finally was recognized as a foodborne disease when an outbreak occurred in Canada in 1981, despite the fact that sporadic cases had been reported a long time before this. Campylobacter enteritis, which is now recognized to be one of the most common causative agents of foodborne illness, similarly was not identified for many years because cases are almost entirely sporadic and detection methods were not available or were not in use.

The continued generation of sound epidemiological and microbiological data is essential if we are to be able to effectively identify new microbiological hazards. The erosion in many countries of the expertise and facilities to carry out epidemiological investigations, mainly as a result of loss of funding, and reduced ability to perform the underpinning microbiology research, needs to reassessed in the light of the clear need for this basic information for MRA. As part of this ongoing activity, there is a need for epidemiological surveillance of illness within populations to identify potential new problems and to better quantify the extent of existing ones; sentinel studies are particularly useful in this regard (see Chapter 37). Also, targeted surveillance of foods for specific microorganisms needs to be an ongoing activity recognizing that new foods, new food sources, and new processing and packaging methods will continue to be developed to meet the changing tastes and expectations of consumers throughout the world—activities that may give rise to new microbiological hazards.

Further, all existing knowledge on microbiological hazards needs to be incorporated into readily accessible databases that can be updated as new information becomes available; the Internet is proving to be a useful vehicle for the rapid dissemination of such information. Even in Western countries, much potentially useful epidemiological and surveillance data are not currently accessible to those concerned with the use of such information for hazard identification.[1] The WHO (European region) coordinates and disseminates information on the types of microbial agents reported to cause foodborne illness in many European countries.[78]

Knowledge of factors affecting the growth, survival, and death of established and emerging food pathogens in foodstuffs, and basic studies of their genetics, physiology, and biochemistry are essential for hazard identification and characterization. Considerable progress has been made in recent years in the development of more accurate mathematical models predicting the growth, survival, and death of microorganisms in foods and developing means of making this information widely available in the form of portable computer databases (see Chapter 16). Further development of electronic databases, combining these models with other information on the biology and disease characteristics of these organisms into expert systems, will considerably enhance the usability of these data for nonexpert hazard identification, a particular need for use in the hazard analysis stage of HACCP.

Summary. There is a need to improve the collection and dissemination of information on the microbiological agents involved in foodborne illness, the foods involved, and the circumstances that led to illness. Such epidemiological information should be collected by health authorities throughout the world and made available to national and international bodies concerned with risk assessment.

65.2.3.2 Hazard Characterization

The goal of hazard characterization is to provide a quantitative, or at least a semiquantitative, estimation of the severity and extent of illness caused by the presence of a particular number of microorganisms or an amount of a microbial toxin in a foodstuff at the point of consumption. Thus, when considering hazard characterization, there is a need to consider the availability of dose response data (ie, the probability of illness and the degree of illness caused by a particular concentration of a microorganism or toxin). Specifically, the risk of infection has been defined as the mathematical probability of infection from a given dose of exposure.[61]

There are a number of ways in which knowledge can be obtained of the infective dose. The classic way, and considered by many to be the best, is the use of controlled challenge studies in which a statistically significant group of human volunteers is fed different concentrations of microorganisms and the clinical symptoms observed. This method has been used to generate dose-response data for a range of microorganisms.[68] These have been used in "model" risk assessments mainly by those concerned with the control of microbial diseases that are spread by water or are associated with the consumption of aquatic animals such as mollusks.[30,31,46,58,60,61,62]

Many of the published dose response data have been based on feeding healthy adult, male volunteers (mainly prisoners or students).[68] However, data obtained from incidents of foodborne illness indicate that many of these data give low estimates of the probability of illness from particular concentrations of pathogenic microorganisms. For example, results of feeding trials using salmonellas suggest that a minimum dose of 10^5 is necessary to cause illness, whereas there is much evidence that under some circumstances widespread illness can result from the consumption of as few as 10 cells (see Chapter 45). Some of the reasons for such differences, in addition to age and health status, are listed in Table 65–2 and include microbiological factors such as variability in the virulence of strains within a particular microbial species, the influence of a particular food type, or other microorganisms on survival through the intestinal tract or on the production of virulence factors. Important factors affecting the susceptibility of the host include health, nutritional and immunological status of the individual, status of digestive tract at time of consumption of a contaminated food, and the possession of certain human antigenic determinants in the body fluids.

A further method of obtaining dose response data is to collect information on the number of a microorganism/amount of toxin present in a food implicated in a foodborne illness incident, and to relate such information to the percentage of persons with symptoms and the seriousness of the symptoms observed. The information generated by this means is likely to be more realistic than that generated by volunteer studies but most of the same constraints apply, as do some additional ones—for instance, the poor accuracy and reliability of the microbiological data obtained from the analysis of a food, sometimes days or even weeks after the food caused illness, recognizing that the food may have been stored under conditions allowing microbial numbers or an amount of a microbial toxin to change. Further, while such data may give some information on the minimum infective dose (MID) in a particular food, it is unlikely to provide dose-response data or data relating infectivity or severity of illness to dose. Data relating dose to severity may be obtained by statistically analyzing the results of a number of separate incidents involving the same organism. Thus Glynn and Bradley[29] analyzed epidemiological data from 68 outbreaks of typhoid and 49 outbreaks of salmonellosis. Based on reported severity (ie, number of patients hospitalized compared with total number affected), they concluded that there was a dose-response relationship for severity of disease caused by nontyphoid-causing salmonellas but not by *Salmonella typhi*; a possible reason for not demonstrating a relationship for *S. typhi* is the severity of illness caused by low doses of this organism.

Through the methods outlined above (ie, feeding trials and retrospective analysis of outbreak data), it is possible to develop probability models to estimate the risk of infection resulting from exposure to different concentrations of microorganisms. The development of such models for foodborne pathogens is still a relatively new development, although the beta-distributed infectivity probability model or simply the Beta-Poisson model, which is the basis of most such models, was described in the early 1980s by Haas.[30,31]

The Beta-Poisson model is described by the equation $P_i = 1-(1+(N/b))^{-a}$; where P_i is the probability that an individual exposed to an average dose of N organisms will become infected, and a and b are parameters that define the dose response curve.[30,31,61] This model was found to most closely fit dose-response data from human feeding trials.[31] Two other models, a log normal and an exponential model, examined by Haas did not so closely fit the feeding trial data. The Beta-Poisson model assumes that a single bacterium or virus particle is capable of initiating infection, that there is a Poisson distribution of cells or particles in replicate doses, and that there is a distribution of probabilities that an agent, once ingested, will survive and initiate infection, a process that is mathematically described by the beta distribution.

The use of the beta-distribution infectivity model to generate data on the probability of infection resulting from exposure to different concentrations of microorganisms has been criticized because it makes several assumptions that are not likely to be correct. The first is that it assumes a random (Poisson) distribution of microorganisms in a water source or foodstuff (a possibility for the former but highly unlikely for the latter); the second is that susceptibility to illness is normally distributed in a population, which is highly unlikely for the reasons listed in Table 65–2. Despite these limitations, some interesting probability estimates of illness have been obtained.[30,61,68] An example of one of these estimates is shown in Table 65–3.

Table 65–3 illustrates the effects of dose (quantity of infectious agent) and the relative virulence of two pathogens (rotavirus and Hepatitis A virus [HAV]) on the probability of infection, illness, and death among a population consuming shellfish.[61] To arrive at their estimate, the following was assumed:

- the Poisson distribution of virus particles in the shellfish
- the shellfish was consumed raw and 60g (six small shellfish) represented a single serving
- the enterovirus levels measured in various surveys of shellfish could be averaged to represent

Table 65–2 Factors Increasing the Risk of Foodborne Infection or the Severity of Illness

Factors	*Reasons*
Microbial factors	
Type and strain of pathogen ingested	Some pathogens and strains more virulent than others
Quantity of pathogen ingested	Higher numbers ingested may increase severity of illness and/or shorten onset time
Host factors	
Age less than 5 years	Lack of developed immune systems, smaller infective dose-by-weight required
Age greater than 50 or 60 years (depending on pathogen)	Immune systems failing, weakened by chronic ailments, occurring as early as 50 to 60 years of age
Pregnancy	Altered immunity during pregnancy
Hospitalized people	Immune systems weakened by other diseases or injuries or at risk of exposure to antibiotic-resistant strains
Concomitant infections	Overloaded or damaged immune systems
Consumption of antibiotics	Alteration of normal intestinal microflora
Excessive iron in blood	Iron in blood serving as nutrient for certain organisms
Reduced liver/kidney function (alcoholism)	Reduced digestion capabilities, altered blood-iron concentrations
Possession of certain human antigenic determinants duplicated or easily mimicked by microorganisms	Predisposition to chronic illnesses (sequelae)
Surgical removal of portions of stomach or intestines	Reduction in normal defensive systems against infection
Immunocompromised individuals including those on chemotherapy or radiation therapy; recipients of organ transplants taking immunocompromising drugs; persons with leukemia, AIDS, or other illnesses	Immune system inadequate to prevent infection
Stress	Body metabolism changes allowing easier establishment of pathogens, or lower dose of toxin required for illness
Poor hygiene	Increased likelihood of ingestion of pathogens
Diet related factors	
Nutritional deficiencies either through poor absorption of food (mostly ill or elderly persons) or unavailability of adequate food supply (starving people)	Inadequate strength to build up resistance and/or consumption of poor-quality food ingredients, which may contain pathogens
Consumption of antacids	Increased pH of stomach
Consumption of large volume of liquids, including water	Dilution of acids in the stomach and rapid transit through the stomach
Ingestion of fatty foods (such as chocolate, or cheese) containing pathogens	Protection of pathogens by the fat against stomach acids
Other factors	
Geographic location	Likelihood of exposure to endemic virulent strains, limited food and water supply, varied distribution of organisms in water and soil

an average exposure for a variety of enteric viruses

- the echovirus and rotavirus dose-response models represented moderately and highly infectious viruses, respectively; a previous model of echovirus-12 was used to develop the estimate for risk of infection by HAV.

The data indicated that as the level of either virus increased in the 60g serving of shellfish the risk of infection, illness, and death increased. The risk of infection was higher for rotavirus, but the risk of death is slightly higher for HAV. However, these data do not bring out other factors that are important in the pattern of illness shown by these two viruses. For

Table 65–3 Risks of Infection, Morbidity, and Mortality for Consumption of Viral-Contaminated Raw Shellfish for a Single Exposure[*]

	Risk of Infection		*Risk of Illness*		*Risk of Death*	
Viral Levels 60 g^{-1}[†]	*RV*[‡]	*HAV*[§]	*RV*	*HAV*	*RV*	*HAV*
000.1	0.054	0.0002	0.032	0.00015	0.000003	0.0000009
1.0	0.27	0.002	0.16	0.0015	0.000016	0.000009
10.0	0.57	0.02	0.34	0.015	0.000034	0.00009
100.0	0.76	0.15	0.46	0.11	0.000046	0.00066

[*] The risk is the fraction of the population who are likely to experience the consequences (infection, illness, or death).

[†] Single serving of six shellfish.

[‡] RV = rotavirus.

[§] This assumes that the infectivity of Hepatitis A virus (HAV) is equal to the Echovirus-12 model, which is more moderate than the rotavirus. The mortality for HAV, however, is much more significant than for rotavirus.

example, the risk of illness from HAV is lower among children than among adults, whereas the risk of illness from rotavirus is higher among children.[20,28] The reason for this is host resistance (eg, immune status) and is an example of a model not containing complete information on factors affecting infectivity (Table 65–2) that may lead to misleading conclusions. It is important that such modeling of dose and risk is further developed to take account of these additional factors as this information is essential in the assessment of microbial risk.

The final type of information to consider is the use of expert judgment to obtain an estimate of the likelihood and extent of illness when exposed to different concentrations of microorganisms. The publication of part of a large US Food and Drug Administration study[47] is illustrative of this approach. In this study, a group of experts on foodborne pathogens was asked to consider the likely outcome, in terms of absence of illness, or where illness occurs the severity of illness, when a population is exposed to different concentrations of foodborne pathogens. The data obtained were subjected to computer analysis to estimate variances in responses obtained and to quantify the uncertainty associated with each probability judgment. This technique has some possibilities, but the results obtained demonstrated the considerable divergence of opinion among experts, even when they are given the same information and asked to use it as the basis of their estimates. It was concluded that this technique is not a substitute for actual data on dose-response relationships.

The use of animals for hazard assessment has not been discussed because the consensus view among experts on microbial disease assessment is that extrapolation of animal dose-response data to humans is not useful because of the highly variable response of animal models, the exception being primates. Animal models are, however, useful for studying disease mechanisms.

The use of the concept of a MID for a microorganism as an expression of the lowest number of microorganisms able to cause infection, and hence potential to cause disease, is currently regarded to be of limited use for hazard characterization of a pathogenic microorganism.[1] First, in practice, it is impossible to measure, and second, it seems reasonable to assume that each cell of a pathogenic microorganism has the potential to initiate infection and to cause disease in an individual; the greater the virulence of a microorganism, the greater this likelihood. Whether or not infection and subsequent disease occur depends on the number of individuals who are exposed to the organism (ie, the greater the number, the higher the probability that an organism will be ingested by a sensitive individual and cause infection). In risk assessment, it is the risk of infection in a given population or subpopulation that is of main concern, ***not*** the risk of infection of an individual.

Summary. There are a number of practical means of collecting data suitable for the characterization of a microbiological hazard but all have limitations. There is a need to develop better data and dose-response models that can take account of the many factors affecting infectivity and the development of foodborne illness.

65.2.3.3 Exposure Assessment

The aim of exposure assessment is to evaluate the degree of human exposure to a microbial pathogen or toxin that is likely to occur as a result of food consumption. Thus it concerns obtaining knowledge of the numbers and types of foodborne pathogens and microbial toxins that may be present in food(s) at the point of consumption. It must consider changes in numbers of pathogens present in raw materials and/or products or introduced as a result of contamination during processing, storage, or preparation for consumption. With regard to toxins, consideration must be given to the conditions necessary for toxin production pre- and postharvesting and during any manufacturing or distribution procedure. Conditions leading to destruction of toxins during processing or preparation of a food for consumption must also be considered.

Data on the occurrence of foodborne illness-causing microorganisms in raw and processed foodstuffs have been collected and analyzed by many bodies. What they broadly indicate is that virtually any animal, plant, or environment-occurring pathogen may be found on raw agricultural products with variable and largely unpredictable frequency and amount. This will depend on where the product is grown, how well it is protected from contamination during growing and harvesting, and how well it is handled during subsequent handling prior to consumption. With most processed foods, much less variation will be found, provided they are produced under conditions where Good Manufacturing Practices (GMP) and HACCP are properly applied and storage conditions are well controlled. Data on the occurrence of microorganisms on foods after manufacture can be obtained by the surveillance of foods in the marketplace. However, in order that useful results are obtained from a surveillance program, it is important that statistically based sampling plans are used that take account of the likely frequency of occurrence of the target pathogen(s) in the foods under surveillance, and that the foods sampled are representative of those to which a population would usually be exposed; for further information on the choice of sampling plans for the surveillance of foods for microbiological contaminants, see Chapter 60.

Computer-based mathematical models that predict microbial growth and death in foods when subjected to changing conditions of temperature, for example, are potentially useful for studying the patterns of growth and survival of pathogenic microorganisms in foods throughout the food chain and therefore may provide predictions of numbers of microorganisms in a food at the point of consumption (see Chapter 16).[10,48,50,57,76] However, information on numbers of microorganisms in raw materials, introduced during processing, together with conditions such as temperatures likely to be encountered by a food during distribution, or retailing, will not be generally available and will severely limit the use of such models in exposure assessments. Also, many of the conditions affecting the growth and survival of microorganisms in foodstuffs have yet to modeled. Thus, any estimates of exposure made using such models would need to be checked against actual data. Predictive models are much more useful in HACCP studies than exposure assessments.

Other practical problems limiting the accuracy of exposure assessments include:

- failure to detect microorganisms damaged in some way so that they are not detectable using standard microbiological techniques;
- general heterogeneity in the distribution of microorganisms in foodstuffs making their accurate estimation difficult;[42]
- many potential sources of microbial contamination of foods as they proceed along the food chain, making estimates of likely numbers in foods at point of consumption even more inaccurate;
- changing population demographics and consumption patterns of foods; and
- introduction of new foods, new preservation systems, and new cooking procedures (such as microwave cooking) that may change the degree of exposure of the food consumer to particular pathogens (eg, psychrotrophic pathogens such as listeria, yersinia, and nonproteolytic *C. botulinum* in extended shelf-life, chill-stored foods).

In the absence of sound data on exposure of a foodborne pathogen to a population, a regulatory authority making a risk assessment will wish to err on the side of caution. Thus, when in the early 1980s *Listeria monocytogenes* caused several large outbreaks of listeriosis, several regulatory agencies introduced regulations requiring the absence of the organism from ready-to-eat foods. However, when it was subsequently found that *L. monocytogenes* was a common contaminate of food, a number of these authorities[26,67] revised their risk estimates, accepting that for most foods intended for general consumption, total absence was not necessary to protect the health of the consumer.

Summary. Exposure assessment of foodborne pathogens and toxins is difficult, and largely uncertain, because of the numerous opportunities throughout the food chain for microbiological contamination to occur; unprocessed foods are particularly subject to contamination by a wide range of pathogenic microorganisms. The heterogeneous distribution of pathogenic microorganisms and their toxins in most foodstuffs makes the accurate estimate of amounts difficult, and their changing concentrations with time make estimates of exposure at the point of consumption even more difficult.

65.2.3.4 Risk Characterization

Risk characterization is the final step of the risk assessment process, where all the information collected and collated in the three previous steps is assessed. Its aim is to give an estimate of the probability of occurrence of illness (including a description of any statistical and biological uncertainties) within a given population, taking into account the severity of illness likely to be caused, the number of organisms or the amount of toxin needed to cause illness (hazard characterization), and an assessment of the likelihood of exposure of members of the population (exposure assessment).

By way of example of applying risk characterization and the potential use of the four-step process of risk assessment to assess microbial risks, we will consider three examples of microbiological risk assessment.

The first is one of a series of examples presented by Todd and Harwig[71] of model risk assessments of foods distributed in Canada. To identify the microbiological hazards associated with meat and poultry products (hazard identification), they reviewed the available epidemiological information (number of cases, severity of illness, sections of population particularly at risk) on illnesses arising from the consumption of these foods and selected those organisms they considered to be most significant in terms of human morbidity and mortality. These were salmonellas, campylobacters, verocytotoxigenic *Escherichia coli*, *L. monocytogenes*, and *Toxoplasma gondii*.

For the second step of the assessment process (hazard characterization), they selected salmonella and toxoplasma to serve as examples. For salmonellas, they collected information on contamination rates on different meat products in Canada, including information on the percentage of carcasses and cuts contaminated, and sources and routes of contamination. They established an average contamination rate for poultry of 75% and for other meats of 5%. Contamination levels on raw meats were assumed to be low (eg, for poultry a level of 1 to 30 cells cm^{-2} was used based on data established by other workers). They did not estimate reductions achievable by cooking or the potential for recontamination, but recognized that these were additional factors to be considered in a risk assessment.

They estimated that 90% of the population of Canada (ie, 27 million) consumed chicken and other meat products. Thus, they calculated that the population exposed to salmonella from poultry is $75\% \times 90\% \times 27 = 18.2$ million and for raw meats $5\% \times 90\% \times 27 = 1.2$ million. This is an oversimplification of exposure as it does not take into account frequency of consumption of the different meats, or amounts consumed by different population groups or how the products might be prepared for consumption.

Although Todd and Harwig did not recognize a risk characterization stage in their analysis, they did attempt a risk estimate for each of the organisms they considered. Thus, based on other data, they stated that about half of the estimated 627,200 cases of salmonellosis in Canada each year arise from the consumption of meat, with about 36% of cases from poultry and 12% from other meats; this gave an estimated number of poultry- and meat-derived cases to be 227,000 and 76,000, respectively. From the information on the population exposed to salmonellas, they calculated the ratio of ill to at-risk cases for poultry meat as 1 in 80 (227,000/18.2 million) and for other meats as 1 in 16 (76,000/1.2 million). This led to the interesting conclusion, based on their assumptions and estimates, that although red meats are 15 times less likely to be contaminated with salmonella than poultry meat, they are 5 times more likely to cause salmonellosis. One possible explanation for this could the tendency to undercook red meats. If so, a risk management strategy derived from such a study might be to encourage more thorough cooking of these products.

A second example of the application of the risk assessment procedure is an estimate of the risk of viral infection from consuming raw shellfish harvested from approved waters in the United States.[61] As discussed previously (Section 65.2.3.3), probability estimate models for echovirus-12 and rotavirus were used to assess the risk of an individual becoming ill after consuming a single serving of shellfish. The estimated risk of illness was 1 in 100 if echovirus-12 (a moderately infectious virus) was present; this increased to 5 in 10 if a highly infectious virus, such as rotavirus, was present at a concentration of 100 virus particles/serving.

In a third example of risk assessment, the public health significance of cracked eggs was assessed.[70] Based on epidemiological information and literature searches, it was concluded that *Salmonella* is the only pathogen that has been conclusively linked with illness from cracked eggs. Of the eggs graded in Canada, about 2.5% were in the category that includes cracked eggs. It was estimated that there are approximately 143 million cracked eggs produced in Canada each year, and an estimated 10,500 cases of salmonellosis resulted from their consumption. Cracked eggs were estimated to be between 3 and 93 times more likely to cause salmonellosis than uncracked eggs. On average, the risk of illness from consuming contents of cracked eggs was estimated to be 1 in 3,800; however, some sectors of the population would be at a higher risk. A detailed risk assessment of *S. enteritidis* in shell eggs and egg products is contained in a recent US Department of Agriculture (USDA) report.[5]

A number of risk assessments have been described recently using computer simulation models to predict the effect of processing and storage regimes on microbial growth and survival in specific foods.[10,48–50,57,76,77] These models take information on the concentration and distribution of a particular microorganism in, for instance, a raw material and based on knowledge of the effect of processing and storage conditions are able to predict likely changes in numbers from a production stage to consumption and to predict the number of organisms that could be consumed.

The most recent of these risk assessments[10,57,77] interface such predictions with infective-dose models and are thus able to predict the chance of infection from consumption of a portion of food contaminated with a particular concentration of a microorganism. However, as noted previously, the amount of specific data required to use such models is very high. This includes, for instance, knowledge of the range and distribution of the target microorganism in a material to be processed and the kinetics of any destruction process or condition permitting growth to occur during or after a production process.[10,50] Thus their use appears limited mainly to specific food operations. Here, they are able to provide quantification to the hazard analysis process of HACCP as well as being useful to explore the impact of different process and product formulation options on the microbial risks of manufactured foods.

Summary. Microbiological risk assessment is a fast-developing field of quantitative microbiology. Estimates of risk are likely to be inaccurate for the reasons explained; however, the four-step risk assessment procedure described can be used to semiquantify, rank, and compare microbiological risks.

65.3 MICROBIOLOGICAL AND RELATED CRITERIA

65.3.1 Background

Several different types of criteria are used by food microbiologists to manage and control microbiological risks. The first and most commonly used are ***Microbiological Criteria***, which are used as the basis for deciding whether the concentrations of specific and general types of microorganisms and toxins measured in a foodstuff are acceptable or not. Such criteria may be classified into microbiological standards, specifications, and guidelines to reflect their different and varied use by industry and the regulatory authorities as risk management tools. They are applied usually to ingredients and finished products and less commonly to foods while in the process of manufacture.

The second group of criteria are ***Performance*** and ***Process Criteria***. These are applied during the production of a food with the aim of building into the manufacturing process effective measures to control the risks of identified microbiological hazards to acceptable (safe) levels.[37] A performance criterion has been described as the outcome of one or more control measures at a step (eg, operation, processing step, or stage in the food chain) or a combination of steps intended to ensure the safety of a food. For example, a 12D kill of *Clostridium botulinum* spores in a sterilized canned food, or defined composition and/or storage conditions (eg, formulation, time and temperature of storage, type of packing) of a perishable food to prevent a 1 log increase in growth of a pathogen. Process criteria are the control parameters (ie, the specific temperature, time, pH, a_w, etc.) that are applied at a particular step or a combination of steps to meet the performance criterion. For instance 2.5 minutes at 121° C to achieve a 12D kill of *C. botulinum*, a pH of 4.6 or less in a canned food to prevent the growth of *C. botulinum* in an acidified

Next Page

canned food. Process criteria may be used by food producers as control measures (Critical Limits) at specific critical control points (CCPs) and thus may be widely applied in HACCP plans.

Both performance and process criteria may also be specified by regulatory agencies as mandatory or advisory control measures. For example, many regulations specify a heat treatment for the pasteurization of milk at 71.7° C for 15 seconds. There is growing interest among regulators in some countries to establish further process and performance criteria based on risk analysis and to require industry to design and manage their processes to meet these through the application of GMP and HACCP. Examples include performance criteria for juice products and meat and poultry products.[27,75]

The following are examples of the application of microbiological, performance, and process criteria; they are intended to demonstrate the relationships between these types of criteria as control measures. The first is a series of options for the control of *C. botulinum* in preprepared chill-stored perishable foods recommended in a report by the UK Advisory Committee on the Microbiological Safety of Food.[2] These options were:

1. A heat treatment of 90° C for 10 minutes or equivalent lethality
2. A pH of 5 or less throughout the food and throughout all components of complex foods
3. An a_w of 0.97 or less throughout the food and throughout all components of complex foods
4. A combination of heat and preservative factors that can be shown consistently to prevent growth and toxin production by *C. botulinum.*

Option 1 is a process criterion directed toward killing vegetative cells and spores of psychrotrophic strains of *C. botulinum* that may be present in the raw materials used in the production of the foodstuff. Options 2 and 3 are further process criteria intended to prevent the growth of vegetative cells of this organism and hence prevent toxin production. Option 4 could involve thermal destruction/thermal injury of spores and inhibitory factors to prevent the outgrowth of surviving *C. botulinum* spores.

Underlying each process criterion option is an unstated performance criterion. Thus the performance criterion for option one could be stated as a 6D reduction of spores of psychrotrophic strains of *C. botulinum* as this is the intended result of a heat treatment of 10 minutes at 90° C. For options 2 and 3, the performance criterion could be stated as less than 1 log increase of *C. botulinum* within the use-by date when stored at the recommended storage temperature. Thus performance criteria do not describe how to control risk, but rather specify the end result that must be obtained. Process criteria specify the control parameters that can be applied to achieve the performance criteria.

The second example concerns the risk of *E. coli* O157:H7 and similar foodborne pathogens in fermented sausages. In December 1994, an outbreak of foodborne illness caused by *E. coli* O157:H7 occurred on the West coast of the United States (US) that was attributed to a fermented sausage product. In response, the USDA proposed a requirement that all manufacturers must use processes that will control the risk of illness from *E. coli* O157:H7. In this case, the agency proposed a performance criterion (ie, 5D kill of *E. coli* O157:H7) and left it to industry to decide how to satisfy the criterion and still produce products of acceptable quality. The agency's proposal of a 5D kill was based on very limited evidence suggesting that up to 1,000 g^{-1} of *E. coli* O157:H7 could occur in the raw meat used for processing. On the basis of industry-sponsored research, five options were developed and accepted by the agency.[54]

1. Apply an existing, approved heat treatment specified in USDA regulation 9CFR 318.17 (ie, heating to an internal temperature of 62.8° C or to a lower temperature for such time necessary to obtain an equivalent level of safety).
2. Apply a process that is validated by research to cause a 5D kill of *E. coli* O157:H7 before the product is released for distribution.
3. Combine raw material testing with a process that is validated by research to cause a 2D kill of *E. coli* O157:H7 before the product is released for shipment. The sampling procedure must ensure the level of *E. coli* O157:H7 in the raw sausage blend does not exceed 1 g^{-1}. One such sampling plan could consist of analyzing 15 sample units (25g each) collected at the same time the sausage blend is stuffed into the casings.
4. Apply a hold and test program for the finished product before distribution. Products intended to be heated before serving (eg, pepperoni for pizza) would be sampled at a rate of 15 sample units per lot. Products normally consumed without heating before serving (eg, salami) would be sampled at a rate of 30 samples per lot. The analytical unit for each sample unit tested would consist of 25g.
5. To allow for new technology or ideas, this option permits the use of alternate processes that

ensure the level of *E. coli* O157:H7 will not exceed 1 100 g^{-1}.

All five options are intended to yield no greater than 1 *E. coli* O157:H7 $100g^{-1}$ when the products are released for distribution. This was considered by the USDA at the time to be an acceptable level of risk for this class of product. The five options include process criteria, performance criteria, and microbiological criteria. Options 1 and 2 assume an initial level of 1,000 *E. coli* O157:H7 g^{-1} in the raw sausage blend. The process criterion for option 1 (heating to an internal temperature of 62.8° C) is derived from an existing regulation for roast beef and is based on research data demonstrating that this will result in a 5D kill of *E. coli* O157:H7 in beef; processors choosing this option would not take advantage of the faster rate of kill that would occur with the reduced pH of a fermented product.

The performance criterion in option 2 specifies a 5D kill of *E. coli* O157:H7. To satisfy this option, the processing plant must have on file, and available for review, research data that validate that the process being used will achieve the 5D kill; the research protocol for validating the process must be approved by the USDA.

Option 3 makes use of both a performance and microbiological criterion. Thus it involves a performance criterion of a 2D kill, in combination with microbiological testing to verify that the level of *E. coli* O157:H7, in each production lot, does not exceed 1 g^{-1} in the raw sausage blend; collectively, the net result is equivalent to the 5D kill of option 2, which assumes an initial level of 1,000 g^{-1} in the raw sausage blend.

Option 4 establishes microbiological criteria for the product and assumes no prior knowledge of the level of *E. coli* O157:H7 in the raw sausage blend or the lethality of the process. Reliance is placed solely on the use of a sampling plan that may detect *E. coli* O157:H7 if it is present in the finished product.

It is an historical fact that the major advances in public health have been made by applying interventions, such as the use of milk pasteurization or water chlorination to control specific microbiological hazards, ie, application of performance and process criterion. We are not aware where significant foodborne hazards to health have been reduced through the application of a microbiological criterion to a foodstuff as the primary means of control. In 1970, Sir Grahame Wilson, when summarizing a meeting on the use of microbiological criteria, stated: "Bacteriologists are better employed in devising means to prevent or overcome contamination than in examining more and more samples. Processing concerns the whole volume of food, sampling only a minute fraction of it."[79]

The pros and cons of relying on microbiological criteria to ensure microbiological safety will be addressed in the remainder of this chapter. For further consideration of management of microbiological hazards based on the use of Process and Performance Criteria, see ICMSF (1998).[37]

65.3.2 Definitions of Microbiological Criteria

Many definitions have been proposed for microbiological criteria.[35,56] The most recent of these, proposed in the Codex Alimentarius Commission's document on "Principles for the Establishment and Application of Microbiological Criteria for Foods,"[18,25] states that "A microbiological criterion defines the acceptability of a product or a food lot, based on the absence or presence, or number of microorganisms including parasites, and/or quantity of their toxins/metabolites, per unit(s) of mass, volume, area or lot." This document separates such criteria according to their application by regulatory authorities and by industry but does not specifically name them according to usage; however, it is convenient to do so, and three types of microbiological criteria are generally recognized according to their use.[56] These are:

- **Microbiological Standard.** A mandatory criterion that is part of a law or ordinance.
- **Microbiological Specification.** Part of a purchasing agreement between a buyer and vendor of a food; such a criterion may be mandatory or advisory according to its use.
- **Microbiological Guideline.** A criterion used by a food producer to monitor microbiological conditions during the production of a food; such a criterion would be advisory and intended for internal use. Such a criterion could also be used as part of the verification process of HACCP.

65.3.3 Establishment of Microbiological Criteria

65.3.3.1 Need and Applicability

When considering establishing a microbiological criterion for a foodstuff or a range of foods, the first consideration should be that of need (eg, is there a health hazard associated with the food(s)?). The second equally important question that should be asked is: Will the criterion serve a useful function? For instance, a regulatory authority should consider whether the introduction of a criterion would have a positive health benefit (ie, reduce the risk of foodborne illness). A food producer may also wish to consider whether the application of a microbiological criterion would reduce the risk of spoilage. A third question that should be asked concerning application is: Is a microbiological criterion the best, or only, means of ensuring that a foodstuff is microbiologically safe or stable?

A regulatory authority wishing to establish a microbiological standard for a food should consider such need on evidence of a health concern derived from a full risk assessment or sound evidence of a public health concern.[18] Options for control should be considered as part of the process of risk management. One option may be in the form of a Food Safety Objective.[22] This has been defined by the ICMSF as "a statement of the frequency or maximum level of a microbiological hazard considered acceptable for consumer protection."[37] A microbiological criterion may be derived from a Food Safety Objective.

A food producer wishing to determine need should consider what public health concerns have been associated with the product or raw material(s) used, and is there microbiological or trade data indicating a significant spoilage problem with the intended product? He or she may also consider with respect to need:

- What is the potential for presence of pathogenic microorganisms in the raw materials?
- What is the effect of any processing on these (ie, will they survive or grow)?
- What is the potential for cross-contamination and growth of pathogenic microorganisms in the product?
- How will the product be distributed and how will it be used?

These questions are discussed in detail in Section 65.3.3.

Having established that there are one or more significant microbiological hazards associated with a foodstuff, the food producer must consider options for control. The questions that should be asked are:

- What numbers of microorganisms/amounts of toxins need to be controlled? Acceptable limits may be derived from legal limits or from recommendations of recognized bodies such as the ICMSF or the US National Advisory Committee on Microbiological Criteria for Food.
- With what degree of certainty should this control be exercised?
- What options are available for their control and how effective are these likely to be?
- Where should and can these control options be applied?

Consideration of the answers to these questions will help to clarify the need, content, and role of a criterion. For instance, it might be concluded that a microbiological safety or shelf-life concern is best controlled by designing or modifying a production process to eliminate a hazard(s) or to control it to an acceptable level, which, if successful, may mean that the use of a microbiological criterion as a means of control is not necessary, and a more effective means of control may be applied, such as the use of HACCP with control measures based on Performance and Process Criteria.[37]

As an example of the sort of considerations that should apply when considering options for the microbiological control of a product, we will consider the establishment of control measures for mayonnaise manufacture. The microbiological hazards and risks arising from the egg used in such a product could be avoided by the use of pasteurized egg purchased from an audited and approved source applying GMP and HACCP, or by purchasing egg from a less secure (and perhaps cheaper) source and using a microbiological criterion to clear the egg prior to use. However, the second option is likely to provide much less security than the first (because of poor assurance of detecting contaminated lots by microbiological testing) (Table 65–4). It may be decided, therefore, not to test, but to either reconsider the use of pasteurized egg or to reformulate the mayonnaise so that any pathogens of concern (eg, salmonellas) would be destroyed in the formulated product.

Consideration as to whether to apply a microbiological criterion as a control measure is never wasted effort because it is only by considering such options that the real need to use a microbiological criterion as a primary means of control will be identified. More often than not, it will be found that use of a microbiological criterion is the least-preferred control option, and should only be used when other more effective options cannot be applied or are found to be unreliable. Thus, the Codex Alimentarius document on microbiological criteria for foods[18] states, when referring to the application of such criteria, that: "They may be relevant to the examina-

tion of foods, including raw materials and ingredients, of unknown or uncertain origin or when other means of verifying the efficacy of HACCP-based systems and Good Hygienic Practices are not available." Potential uses and misuses of microbiological criteria by the regulatory authorities and by industry are considered in Section 65.3.4.

65.3.3.2 Basis

The basis of establishing a microbiological criterion has been well defined as a result of the combined activities of the ICMSF, FAO/WHO, and the Codex Alimentarius Food Hygiene Committee.[17,18,35] The following list of considerations that should be applied when establishing a microbiological criterion is based on the Codex document.[18] It assumes that the need to establish a criterion for a foodstuff has been established on the basis of the considerations discussed in Section 65.3.3.1.

The Evidence of Actual or Potential Hazards to Health. Although the Codex document[18] only concerns health considerations, spoilage and shelf-life concerns also may be considered for criteria applied by industry.

The Microbiological Status of Raw Material(s). This concerns the quality and type of raw materials used. The numbers and varieties of microorganisms found in raw materials will depend on a number of factors, including the source of the raw material, how it has been produced, and how it has been handled or treated since harvesting or production. Thus, if a raw agricultural product is not subject to any form of processing that might be expected to kill part or all of its microbial flora, the organisms present on that raw material will be more numerous and diverse than if the same raw material were pretreated before use. Thus, the microbial profile of a raw spice would be expected to be very different from that of an irradiated or heat-treated spice; such differences would need to be reflected in any microbiological criterion applied to the raw material or to a product containing this material. Clearly, if such spices were to be used in a ready-to-eat product, the criterion would need to include strict limits for infectious pathogens such as salmonellas. However, because of the poor security obtained by testing a product, even when the criterion requires as many as 60 sample units to be analyzed (see Table 65–4), the producer would be well advised to use only treated spices from an audited and approved source.

The Effect of Processing on the Microbiological Status of the Food. A food product made entirely of raw components will have a microbial flora that reflects the microbiological status of the individual components. Thus, a raw meat product would be expected, from time to time, to be contaminated with low numbers of zoonotic microorganisms such as salmonellas and campylobacters. However desirable it might be to totally avoid the presence of such organisms, it is unrealistic to expect this; any microbiological criterion needs to take this into account. On the other hand, a food made from cooked meat components would be expected to be free from such organisms and to contain fewer other microorganisms; a microbiological criterion should reflect this.

The Likelihood and Consequences of Microbial Contamination and/or Growth during Subsequent Handling, Storage, and Use. One of the most difficult aspects of setting a microbiological criterion is the need to understand sufficiently how any raw food materials and the intermediate and final product may be further contaminated or recontaminated during production, storage, distribution, and preparation for use, and the subsequent fate of such contaminants. Thus the microbial profile of a food product based on the sole consideration of microbes introduced with raw materials and the subsequent effect of processing may give a very inaccurate picture of true microbial profile of the final product. A well-founded HACCP study may provide some additional information, at least concerning potential routes and sources of contamination. Predictive models of microbial growth and survival also will provide useful information on the fate of microorganisms of concern in a food product, but accurate information concerning how a product is handled once it leaves the production site is seldom available and requires assumptions to be made of the likely handling conditions. Figure 65–3 indicates how a decision tree approach may be used to identify the organisms of concern in a chilled food, taking into account the factors mentioned above.

Category(s) of Consumer Concerns. As already discussed in Section 65.2.3.2, the possibility of foodborne illness resulting from the consumption of a contaminated food depends on a multiplicity of factors, including the inherent sensitivity of the consumer. Thus, a food intended for an infant should have a much tighter microbiological criterion than a food intended for an adult. Such a distinction between foods for infants and foods for adults is fine when a food is clearly labeled as infant food, but as many manufacturers have found to their cost, foods intended for consumption by an adult or young person may well be fed to an infant by a busy young mother, resulting in illness among the infants but not among adults consuming the same product. Thus, it is sound practice for a producer to label a food intended for an adult population, if it is not suitable for an infant or other sensitive sector of the population. Examples of such foods are honey, as there is evidence of infant botulism from its consumption (see Chapter 41), and certain types of soft cheeses that should not be consumed by women when pregnant because of the increased risk of listeriosis (see Chapter 44).

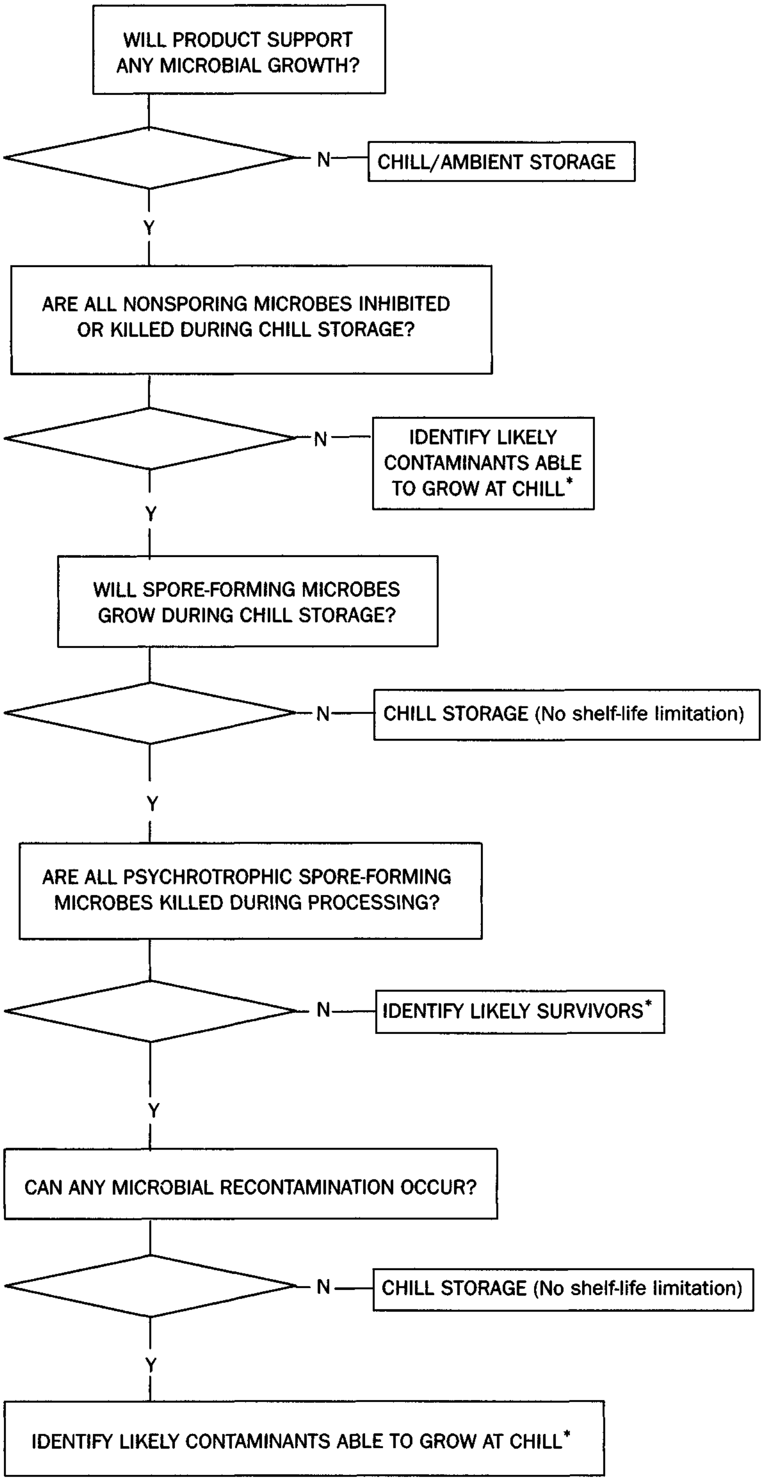
The Cost/Benefit Ratio Associated with the Application of the Criterion. The costs involved in applying a microbiological criterion can be substantial. These include the cost of sampling (manpower and food costs) and performing the microbiological analyses. They may also include costs of transporting the samples to an offsite laboratory for testing; communicating the results of the analysis accurately and in a timely manner so that product can be released or withheld; and the cost of actions arising if a product does not meet the criterion. Such actions may include sorting, reprocessing, or destruction. Usually, substantial costs will be involved in the recovery of product from distribution sites or the marketplace if failure to meet a criterion is identified after a product has entered the distribution chain. Producers who elect to hold product until results of microbiological analysis are available must build this into their inventory control system along with the cost of storage onsite or at an offsite location. This may necessitate double handling at a warehouse or distribution center. For perishable foods, the time the product is held awaiting analytical results is loss of shelf-life time, and this can decrease the geographical distribution area for highly perishable foods. Similar considerations apply when product is held for analysis by an authority at a point-of-entry into a country.

Further costs may arise from the statistics of the sampling plans as these have a defined probability of failure. Such failure may result in faulty product meeting the sampling plan and is called the consumer's risk and is defined by the ICMSF[35] as "the probability that a lot will be accepted on the basis of results of testing analytical samples when in reality the lot as a whole is substandard relative to the stated criteria of acceptability." Failure to meet a sampling plan also may occur with a completely acceptable product and is called the producer's risk and is defined by the ICMSF[35] as "the probability that a lot of acceptable quality will be rejected on the basis of results of testing analytical samples relative to the stated criteria." The statistics of sampling plans, including producer and consumer risk, are discussed in Chapter 60.

It cannot be overemphasized that sole reliance on a microbiological criterion as a means of identifying defective product is likely to have high cost and low benefit. The use of a microbiological criterion as part a quality assurance function based on GMP and HACCP is likely to have a much better cost/benefit ratio and will be considered in Section 65.3.4.2.

65.3.3.3 Components

A microbiological criterion, irrespective of how it will be used, should comprise basic components.[18,25]



WILL PRODUCT SUPPORT ANY MICROBIAL GROWTH?
N
CHILL/AMBIENT STORAGE
Y
ARE ALL NONSPORING MICROBES INHIBITED OR KILLED DURING CHILL STORAGE?
N
IDENTIFY LIKELY CONTAMINANTS ABLE TO GROW AT CHILL*
Y
WILL SPORE-FORMING MICROBES GROW DURING CHILL STORAGE?
N
CHILL STORAGE (No shelf-life limitation)
Y
ARE ALL PSYCHROTROPHIC SPORE-FORMING MICROBES KILLED DURING PROCESSING?
N
IDENTIFY LIKELY SURVIVORS*
Y
CAN ANY MICROBIAL RECONTAMINATION OCCUR?
N
CHILL STORAGE (No shelf-life limitation)
Y
IDENTIFY LIKELY CONTAMINANTS ABLE TO GROW AT CHILL*

*These microbial contaminants are potential microbial hazards and their significance as hazards in a particular chilled food manufacturing operation should be determined by the application of HACCP and options for control (including the use of microbiological criteria) established by this process.

Figure 65–3 Identification of Microbes of Concern in Chill-Stored Food

A Statement of Microorganisms of Concern and/or Their Toxins/Metabolites and the Reason for That Concern. All microbiological agents of potential concern should be considered, including bacteria, fungi, viruses, parasitic protozoa, and toxic algae, together with their spoilage and toxic metabolites such as mycotoxins, pressor amines, and the microbially derived marine toxins. The reasons for inclusion of an agent in a criterion should be given and whether it is included because it is a spoilage organism, shelf-life indicator, hygiene indicator, or direct health concern. Only organisms of direct relevance to the safety or keepability of a particular foodstuff should be included in a criterion. General statements such as "pathogenic microorganisms absent" should not be used.

The Analytical Methods for Their Detection and/or Quantification. There are a number of considerations when selecting analytical methods for use when applying a microbiological criterion.

The first is the reliability of the analytical procedure (ie, its accuracy and repeatability). There have been many studies on the reliability of microbiological methods and their dependency on:

- the counting procedure used—methods based on standard three-tube most probable number techniques have an accuracy of c. +/- 400% (95% confidence interval)[12] whereas direct count techniques have an accuracy of c. +/- 50% for counts of between 30 and 200 CFUs, this dropping to an accuracy of c. +/- 150% for counts below 10 CFUs (95% confidence interval)[11]
- interference by food substrates, sanitizers, and other microorganisms—many foods and food ingredients are markedly inhibitory to some microorganisms (eg, chocolate and spices), and these will particularly affect the detectability of microorganisms in presence/absence tests; the presence of sanitizers such as quaternary ammonium compounds also may reduce detectability of organisms on food processing equipment. Also, the presence of large numbers of other organisms acting either as competitors to growth or making conditions in the growth medium unsuitable for growth can reduce the detectability of an organism
- the degree of injury of the target microorganisms—selective microbiological methods used for counting or detecting specific microorganisms will perform very unreliably if organisms are damaged as a result of exposure to harmful agents such as heat or acid.

Many of the factors affecting the detection or countability of microorganisms can be reduced or eliminated by pretreatment of the material to be analyzed and selection of the method of analysis. The procedures for doing this are discussed in Chapter 62.

The second consideration is the intended use of the method. Thus, if the food is to be examined for compliance with a legal standard, the method used should be that specified in the standard; such a method should be one that has been approved as a reference method by an international standards organization such as ISO,* AOAC,* or CEN,* and should be shown to perform satisfactorily with the foodstuff(s) to which the criterion applies. If such a method does not exist for a particular agent, that agent should not be included in a legally binding microbiological criterion. If the method is to be used as part of a criterion intended for use by industry for internal control purposes only, then a less proven method may be acceptable, particularly if it enables more samples to be examined, and the results to be obtained faster and/or at a reduced cost. In this regard, some of the newer rapid methods may be more applicable (see Chapter 61).

A Plan Defining the Number of Field Samples To Be Taken and the Size of the Analytical Unit. The keystone of any microbiological criterion is the sampling plan, as the operating characteristics of this define the degree of confidence whereby a particular concentration of a microorganism or toxin can be measured or detected.

Sampling plans, as they may be used by industry and public health authorities for the purpose of food lot acceptance, will be mentioned briefly. For detailed information on the statistics of these, and sampling plans used for investigation, survey, or other purposes, the reader should refer to Chapters 58 and 60.

Two types of sampling plan are used for acceptance sampling of food lots: attribute plans and variable plans.

1. Attribute Plans. An Attribute Plan is defined by the ICMSF:[35] "A sampling plan in which each selected sample unit is classified according to the quality characteristics of the product and in which there are only two or three grades of quality; for example, acceptable, defective; absent, present (these are Two-Class Attribute Plans); acceptable, marginally

---

*ISO, International Organization for Standardization; *AOAC*, Association of Official Analytical Chemists; *CEN*, Committee European Normalization.

acceptable, defective; low count, medium count and high count (these are Three-Class Attribute Plans)". Two-Class plans are mainly used for foodborne infectious pathogens, and Three-Class plans for general, indicator, and some toxigenic microorganisms.

Two Class Attribute Plans have a single limit (eg, a microbial concentration) that separates one attribute (eg, an acceptable concentration of a microorganism) from a second attribute (eg, an unacceptable concentration of microorganisms). The decision-making part of such a plan is defined by three letters. The first is represented by the letter n, which is the number of sample units taken from a food lot to be tested; the second is represented by the letter c and is the maximum number of sample units allowed to have concentrations of microorganisms above the acceptable level before the lot of food under test is judged to be defective; the third number is represented by the letter m, which separates an acceptable from an unacceptable concentration of microorganisms.

Thus, a Two-Class Attribute sampling plan for salmonella in a cooked meat product may state: n = 5; c = 0; m = 0; analytical unit (amount of Sample Unit analyzed) 25g. This means that five Sample Units should be taken at random from a food lot and from each of these, 25g taken for analysis. If salmonellas are detected in any of the Sample Units analyzed, the lot fails the criterion.

The difference between a Two-Class and a Three-Class Attribute Plan is that instead of two attribute classes (acceptable and unacceptable), there are three; the third being "marginally acceptable." As the name implies, the marginally acceptable attribute separates the acceptable from the unacceptable. The letter n is used to define the number of sample units to be analyzed from a food lot, but c in a Three-Class plan is the maximum number of marginally acceptable Sample Units acceptable before a food lot is judged to be defective. The m value in a three-class plan becomes the value that separates an acceptable from marginally acceptable concentration of a microorganism or a toxin. A new letter, M, is introduced to separate a marginally acceptable concentration from an unacceptable concentration of an organism or toxin.

There are two particular attributes of Three-Class plans that are not well recognized. The first is that the performance of a Three-Class plan is affected markedly by the distribution of microorganisms in the food lot examined.[35] The second is that there is no fixed relationship between m and M, as the former is set by the performance of a food production plant when operating according to GMP and the latter is based on an expert opinion of the maximum concentration of a pathogen, toxin, or spoilage organism that is considered acceptable in a food, taking into account how that food may be handled and consumed and allowing a certain safety margin. Thus, M is based on a risk assessment and m, by what is achievable by a production plant operating under accepted conditions of GMP. The m value normally would be expected to be at least 10 times less than the M value.

For example, a Three-Class Attribute Plan for *Staphylococcus aureus* in the lot of a cooked meat product may state: n = 5; c = 2; m = 1,000 g^{-1}; M = 10,000 g^{-1}. This means that the cooked meat lot would be acceptable, if three or more of the five analytical units had concentrations of *S. aureus* of equal or less than 1,000 g^{-1} and two or less with concentrations of microorganisms between 1,001 g^{-1} and 10,000 g^{-1} and no analytical unit with a concentration of microorganisms above 10,000 g^{-1}. Three or more analytical units with concentrations of *S. aureus* above 1,000 g^{-1}, and any above 10,000 g^{-1}, would result in the lot being judged to be defective.

2. Variables Plans. The ICMSF[35] describes a Variables Plan as a sampling plan in which the criteria employ the statistics of the sample, such as the mean and standard deviation, rather than the segregation of sample units into attribute classes according to their microbial content as is done when using an Attribute Plan. Such measurement provides the possibility of using a sampling plan with better discrimination between acceptable and defective product lots than is achievable using an Attribute Plan.[43] Their better use is based on the fact that if the distribution of microorganisms in foodstuffs approximates to log normality, the statistics developed for log normal distributions can be applied. However, this limits their use to situations where microbial distributions can be measured; thus, they mainly are used for in-plant testing. For further information on the use of Variables Plans, see Chapter 60.

Microbiological Limits Considered Appropriate to the Food at Specified Point(s) in the Food Chain. For each microorganism or toxin of concern in a foodstuff, one or more limits must be ascribed in the sampling plan. Thus, as noted above, the m value in a Three-Class Attribute Plan should be based on what is achievable in a food operation complying with accepted GMP, whereas the M value in such a plan is a limit corresponding to an unacceptable or hazardous level of contamination. The m value in a

Two-Class Attribute Plan similarly specifies the limit of acceptability.

The *m* limit values in Two-Class Plans and the *M* limits in Three-Class Plans should ideally be derived from some formal risk assessment procedure, such as described in Section 65.2, or when the results of such an assessment are not available, which will usually be the case, on the consensus views of food microbiologists knowledgable of the microbiology of a foodstuff and the significance of particular microorganism(s) of concern. The ICMSF, in its book on microbiological criteria,[35] gives guidance on the choice of limits for *m* and *M* values and provides examples of their application in sampling plans for different types and classes of foods. The limits in these plans are based on the views of food microbiologists from different countries who are expert in the foods and microorganisms of concern. They provide useful guidance for establishing microbiological criteria.

Point in the Food Chain Where the Criterion Applies. The place where a microbiological criterion is to apply must always be specified, as microbial numbers and risk change as a food proceeds along the food supply chain to the consumer. Thus, a food capable of supporting the growth of a particular foodborne pathogen identified in a criterion, and that is likely to be stored at temperatures at which growth could occur, would need to meet a tighter limit when tested at a point-of-entry to a country, and to meet an even tighter limit if tested immediately after production. For example, the ICMSF has recommended that the maximum concentration of *L. monocytogenes* that is acceptable in a ready-to-eat food is 100 g^{-1};[33] this limit is the acceptable concentration at the point of consumption and can be considered to be a food safety objective.[37] Thus, in order that this level is not exceeded in a product supporting the growth of this organism (such as a chilled stored cooked meat product), the concentration acceptable immediately following production will be considerably less than this and, for extended shelf-life products, may require that the production operation is designed and operated so that the organism will be absent and any microbiological criterion should reflect this. The use of mathematical models predicting microbial growth under different storage conditions can provide useful guidance in estimating such changes; see Chapter 16.

There may well be sound arguments that a microbiological criterion is best applied to a food at the point-of-sale, as this would better reflect the microbiological status of the food when offered for sale. However, difficulties arise when food is found to be defective at this late stage in the food chain. For example, some of the product is likely to have been purchased or even consumed. Furthermore it may be difficult to identify where to place the fault (or responsibility) that led to the food failing to meet the criterion. Dispersion of the food lot to many different retailers or food service establishments could make the recovery of a defective lot difficult, if not impossible. Also, although product sampled at one sales point may fail to meet a criterion, this does not necessarily mean that all food from the same food lot is defective; for instance a chilled food lot may be distributed to a number of outlets and due to a failure to control the temperature of the food in one of these outlets, or its distribution chain, the product failed the criterion, yet all other food comprising the lot was correctly handled and therefore not defective. Further, as foods move along the food chain, the discrete identity of production lots is likely to be lost and testing may have to be done on mixed lots, which is likely to further reduce the discriminatory power of a sampling plan as microbial distributions will tend to be more heterogeneous in mixed lots; this may be a particular problem when sampling food in international trade as consignments may contain several food lots.

If samples of food collected at retail are taken for microbiological analysis, the purpose of such sampling should be clear (eg, is this to check whether the production process, or subsequent handling, has been satisfactory, is it part of a microbiological survey to assess the general status of foods in the market, or is it to determine whether a food is safe to eat?). The dynamic nature of microbial populations in many foods needs to recognized when such analyses are assessed. Not only is there likely to be an increase in the total population of microorganisms in perishable foods from the time of production to use-by date, but there also is likely to be a change in the relative proportions of the different organisms making up this population. Thus, it is important that the point in the food chain where a microbiological criterion is to apply is clearly specified and a criterion intended to be applied at one point in the food chain is not applied at another.

Number of Analytical Units That Should Conform to These Limits. The number of Sample Units that should be analyzed for compliance with specified limits will always be a balance between what is desirable to provide confidence that a particular level of contamination is unlikely to be exceeded, and the number that it is feasible to test.

An example of the interrelationship between sample units tested and probability of detection of different levels of contamination in a food lot using Two-Class Attribute Plans (where $c = 0$ and $m = 0$) is presented in Table 65–4.

Clearly, the more sample units that can be tested, the greater the chance of detecting a food lot contaminated, for example, with low levels of salmonellas. Thus, if 1% of units in a food lot were contaminated with salmonellas, and five Sample Units were randomly taken from this food lot and analyzed, there would only be a 5% chance of detecting the salmonellas and rejecting the lot; if 60 Sample Units were examined, the chance of detecting salmonellas would increase to 50%. However, even when 60 Sample Units are analyzed, there is still only a one chance in two of the lot being found contaminated and being rejected. Thus, the limitations of microbiological testing must always be recognized and such limitations taken into account when applying microbiological criteria; no amount of testing can ensure complete safety.

The number of Sample Units specified in a mandatory microbiological criterion (and where specified, the size of the analytical unit) should be adhered to, and not modified, as this will change the performance characteristics of the sampling plan.[18,35] However, in some circumstances, the stringency of a sampling plan used for internal control by industry may need to be tightened; this is usually achieved by increasing the number of Sample Units tested. Circumstances where this may be necessary include where there is no, or only limited, knowledge of the ability of a new supplier of a raw material to meet the microbiological requirements for its use, or when an existing supplier is found to be failing to meet an established criterion. They may also include new production, or a decision by marketing to target a product at a particularly sensitive sector of a population such as young children.

Action To Be Taken When a Criterion Is Not Met. If when tested, a food lot does not comply with the defined criterion of acceptance (as specified in the microbiological criterion), the food should not be repeat tested on the basis that it has a chance of passing the next time. If a product passes a criterion, whereas other information suggests that it should fail, the use of an investigational sampling plan would be more appropriate (see Chapter 60).

A food lot failing to comply with a mandatory microbiological criterion must be rejected for its intended use; however, rejection should not necessarily lead to destruction. An assessment should be made as to whether the defective lot can be sorted, reprocessed, or used for another purpose.[18] Such an assessment should be done only in consultation with people who are knowledgeable of the microbiological risks associated with the defective lot. Additional testing may be appropriate before finally deciding on the disposition of the lot. For example, it may be possible to divide a production lot into sublots according to the time of production and to sample the sublots. One means of doing this is to sample production from each consecutive pallet of a production lot to determine if there is a pattern to the contamination. For instance, the first 4 hours of a production run may be unacceptable due to startup problems. Thus the additional testing may indicate that product from 6 AM to 10 AM is unacceptable. A decision could then be made to reprocess all the product from 6 AM to 12 PM or 2 PM, acknowledging that the sampling plan would be unlikely to detect low levels of defective product. Such a decision should always reflect the nature of the defect and the risk to the consumer of releasing defective product. Failure to meet a criterion used as part of the process of verification of HACCP will require investigation of the process to establish where the failure occurred that led to the defective food lot. This may necessitate modification and revalidation of a CCP.

65.3.4 Uses of Microbiological Criteria

The uses of microbiological criteria are discussed in the following paragraphs. They can be separated broadly into their use by the regulatory authorities, mainly as legal requirements, and their use by industry to meet legal requirements and for internal control purposes. Their uses are listed in Table 65–5.

65.3.4.1 Application by a Regulatory Authority

The main use of a microbiological criterion by a regulatory authority is as a measure of checking that a food offered for sale is likely to be safe to eat. Although regulations will be mainly in the form of mandatory criteria, and will generally apply to product after manufacture, they may apply specifically to product during processing and may not always be mandatory. Four examples, showing the range of usage of microbiological criteria by several different regulatory authorities, are presented and discussed below.

Table 65–5 Uses of Microbiological Criteria

Regulatory Use	*Industry Use*
• Regulations:	• Compliance with regulations
Import control	• Purchasing agreements*
Domestic control	• Establishing an HACCP plan
• Monitoring industry	• Verification of HACCP plan
• Advising industry	• Product/process monitoring

*particularly microbiological specifications

The USDA, in response to outbreaks of *E. coli* O157:H7 associated with ground beef, declared *E. coli* O157:H7 an adulterant, and that ground beef found to contain this pathogen must be withheld, or if distributed, recalled from the market.[74] Because an entire production lot could be subject to recall, the definition of a lot is important. For this regulatory program, a lot was defined as the product produced between two complete cleaning and sanitizing procedures. Thus, if an operation is cleaned and sanitized every 4 hours, then the product produced during the 4-hour period in which the sample was collected would be subject to recall if the sample tested positive. In addition, if the raw ground beef is used as an ingredient in other raw products, these secondary products would be subject to recall. The program involves collecting samples from the grinder as the meat is ground; this is the best available sampling point as the distribution of microorganisms in the meat will be most homogeneous at this stage in the process, and hence *E. coli* O157:H7, if present, most detectable.[42] The samples are collected in federal- and state-inspected establishments, as well as in retail stores where beef is ground for local sale. A single portion of ground beef is collected from the lot. The program has involved application of a sampling plan consisting of $n = 1$; $c = 0$; $m = 0$; the single Analytical Unit is 25g.

During the fiscal period 1995 through 1997, the USDA found 9 lots to be positive out of about 16,500 lots sampled, giving a prevalence rate of approximately 0.05%. Assuming that the contamination of *E. coli* O157:H7 is randomly distributed throughout the ground beef supply, it can be estimated that examination of 600 Sample Units would be necessary for a 95% probability of detecting a contaminated lot, if the level of contamination in the lot is 0.5%. This probability would decrease to 45% if the level of contamination is 0.1%. Thus, since the accumulated data for ground beef have shown a level of contamination of 0.05%, it is evident that a lot acceptance plan based on testing even 100 Sample Units from a lot would have little chance of detecting a defective lot and thus would not alter the risk of distributing contaminated ground beef. This is illustrative of the impossibility of detecting a low level of a highly infectious organism such as *E. coli* O157:H7 in a foodstuff. At best, the USDA regulation sends a message to the meat and retail sectors of the food industry that this pathogen is unique in its public health impact and its presence in ground beef must be prevented to the extent possible.

The second example of the application of a microbiological criterion by a regulatory authority is taken from the European Union Directive on Milk and Milk-based products (EC Directive 92/46).[19] This directive contains a number of microbiological criteria including the criteria for drinking milk, which are reproduced below.

- Raw cow's milk for drinking must meet the following standards after bottling/packaging:
  —Plate count at 30° C (per ml): = or <50,000 (geometric average over a period of 2 months, with at least two samples/month);
  —*Staphylococcus aureus* (per ml): $n = 5$; $c = 2$; $m = 100$; $M = 500$;
  —Salmonella: $n = 5$; $c = 0$; $m = 0$ (analytical unit, 25g);
  —In addition, pathogenic microorganisms and their toxins must not be present in quantities such as to affect the health of consumers.
- In random sampling checks carried out in the treatment establishment, pasteurized milk must meet the following microbiological standards:
  —Pathogenic microorganisms: $n = 5$; $c = 0$; $m = 0$ (analytical unit, 25g);
  —Coliforms (per ml): $n = 5$, $c = 1$, $m = o$, $M = 5$;
  —After incubation at 6° C for 5 days, plate count at 21° C (per ml): $n = 5$, $c = 1$, $m = 50{,}000$, $M = 500{,}000$
- In the random sampling checks carried out in the treatment establishment, sterilized milk and ultra-high temperature (UHT) milk must meet the following standard after incubation at 30° C for 15 days:
  —Plate count (30° C): = or < 10 (per 0.1 ml)
- When the maximum standards and compulsory criteria are exceeded and when subsequent investigation indicates a potential danger to health, the competent authority shall take appropriate measures.

How well does this legislation meet the principles proposed for setting microbiological criteria by the Codex Alimentarius Food Hygiene Committee? The points it does cover in relation to the Codex Principles are: it clearly tells the user what foods the criteria apply to and where the criteria are to be applied; it uses Two- and Three-Class Attribute sampling plans and provides some guidance on frequency of testing; it also informs the milk processor what needs to be done when a product fails to meet the acceptance criteria. While the Directive does not give methods of analysis (except where they are specifically required for a product), the UK Dairy Product (Hygiene) Regulations (1995) that are based on this Directive contain a schedule of methods of analysis. Analyses, when done for legal purposes, would be done in an European Union (EU) reference laboratory. Such a laboratory would be operating to appropriate CEN standards, accredited by an approved body, and would use approved methodology. What the Directive does not do is to always provide information of pathogens of concern. Thus it states "pathogens" absent in 25g; "other pathogens" absent in 25g; and "Pathogenic microorganisms and their toxins must not be present in quantities such as to affect the health of the consumer." Such catch-all requirements should not be included in regulations, and we are pleased to note that they are absent from the UK Regulation based on this Directive.

The Directive also makes use of the concept of mandatory and advisory criteria. Thus, it specifies mandatory criteria for salmonellas and *L. monocytogenes* in milk products requiring product to be withdrawn if these "standards" are exceeded. It then lists a series of sampling plans for organisms "indicative of poor hygiene" (*S. aureus* and *E. coli*) requiring a review of "the implementation of the methods for monitoring and checking critical control points." This is an example of the use of criteria for HACCP verification and requires the authorities to be informed of what corrective procedures have been introduced to prevent the reoccurrence of the fault that led to a count limit being exceeded. It further requires that if specified products are found to contain concentrations of the designated microorganisms above *M*, they should be tested for toxicity (eg, enterotoxin production by *S. aureus*) or pathogenicity (eg, *E. coli* O157:H7) and if these are found to be toxigenic or pathogenic, the product must be withdrawn from sale.

The Directive also has a third category of criteria, "Guidelines," giving sampling plans and limits for "indicator organisms." The Directive states that "These guidelines should help producers in ensuring proper operation of their establishments and in carrying out their own checks on their production."

Thus, this Directive very much follows the spirit of the Codex principles for establishing microbiological criteria. It defines mandatory requirements for pathogens in specified products; the use of organisms indicative of poor hygiene control for the checking of GMP and HACCP; and the use of further organisms (coliforms and "plate count") in "guidelines" to be used solely by manufacturers. This is a good example of the application of the Codex Principles in a regulatory framework.

A third example of the application of microbiological criteria is their use by the Canadian authorities for *L. monocytogenes* control.[26,45] The Canadian policy for this organism incorporates the inspector's opinion of whether a food production plant is applying adequate GMP to control the potential for product contamination. If the inspector concludes that adequate GMPs are not being applied, then environmental samples are collected to assess the probability of finished product being contaminated with pathogens, including *L. monocytogenes*. On the basis of the environmental sample results, the next step may be to sample the finished product. The sampling plan applied is shown in Table 65–6.

This is a sound and measured approach to food control based first on inspection and assessment of GMP, and second, where appropriate, by applying microbiological criteria, based on an estimate of consumer risk.

The fourth example is the USDA Pathogen Reduction: HACCP regulation[73] wherein regulatory performance standards were established for salmonellas on carcasses and in raw ground meat and poultry. The criteria were based on data obtained through nationwide baseline studies and involved a statistical procedure called "the moving sum." This procedure compares the number of positive samples in a series of consecutive samples (called a "window") to an acceptable limit. The frequency of sampling (eg, 1/day, 5/week, or 1/week) is not stated in the regulation but will vary according to a plant's performance (ie, plants having difficulty in meeting the standard would be sampled more frequently by the agency). The number of samples tested (n) and the maximum number of positives permitted (c) were calculated for each meat and poultry category to provide approximately an 80% probability of passing when the plant is operating at the national baseline for the prevalence of salmonellas in the category of product tested (ie, just within the performance standard). Examples of performance stan-

Table 65–6 Canadian Government Sampling Plan for *Listeria monocytogenes* in Ready-to-Eat Food Products

Food Category	*Sampling Plan*
1. Foods that have been linked to listeriosis.	$n = 5$; $c = 0$; $m = 0$; analytical unit, 50g
2. All other RTE foods supporting *L. monocytogenes* growth and having a refrigerated shelf life of >10 days.	$n = 5$; $c = 0$; $m = 0$; analytical unit, 25g
3. RTE foods supporting *L. monocytogenes* and having a refrigerated shelf life of equal or <10 days and all foods not supporting growth.	$n = 5$; $c = o$; $m = 100\ g^{-1}$; analytical units, 5 x 10 g analyzed separately

RTE, ready-to-eat.

Lammerding and J.M. Farber, The Status of *Listeria Monocytogenes* in the Canadian Food Industry, *Dairy, Food and Environmental Sanitation*, Vol. 14, pp. 146–150, © 1994, International Association of Milk, Food and Environmental Sanitarians, Inc. (IAMFES).

dards and sampling plans include: steers/heifers (performance standard, 1%) $n = 82$, $c = 1$; hogs (performance standard, 8.7%), $n = 55$, $c = 6$; and ground chicken (performance standard, 44.6%), $n = 53$, $c = 26$. The "window" for each plant will move chronologically as samples are collected and results become available for each category. Compliance will be based on the most recent series of samples. For example, for steers/heifers there can be no more than 1 positive sample among the last 82 samples tested. If a plant fails to meet a performance standard, it must take immediate action to comply with the standard by reviewing its procedures. If the plant fails to meet the required standard for a second consecutive series of samples, this will require the plant to review its HACCP plan and implement corrective actions. If it fails a third series, this could lead to withdrawal of federal inspectors until such time that the agency approves of written assurances that corrective actions will lead to compliance with the standard. This application of a microbiological criterion is intended to measure the performance of a plant's pathogen control measures over time by testing for a pathogen (salmonella). If the original baseline data are valid, then plants that have contamination levels in the top 20% will be forced to make corrections or will be closed. There are, however, a number of uncertainties associated with the designated performance standards, including failure to take account of seasonal and regional differences during the baseline studies. This regulation was only implemented in January 1998, and whether it will result in a reduction in disease from salmonella and other enteric pathogens has yet to be determined.

Summary. A mandatory microbiological criterion should only be applied by a regulatory authority when there is documented evidence that a food is likely to contain microorganisms or toxins that are a hazard to health and that other measures are likely to give less effective control. Legal requirements for limits for foodborne pathogens and toxins should be based on risk assessment. For reasons described and shown above, the sole reliance on a testing for compliance with a microbiological criterion can never provide proper consumer protection. The regulatory authorities should continue to encourage industry to apply GMP and HACCP as the primary means of microbiological control because this will give much greater assurance of microbiological safety than microbiological testing to detect contaminated product.

65.3.4.2 Application by Industry

Microbiological criteria may be used by industry for compliance with regulations, as part of a purchasing specification, and establishing and verification of HACCP. The procedures described here may also be followed by governmental agencies purchasing foods for the military, hospitals, welfare programs, schools, etc.

Compliance with Regulations. A producer may use the same microbiological criterion for internal control purposes as that required in a regulation. However, because of the heterogeneity of distributions of microorganisms and toxins in most foods, the variable performance of microbiological analytical methods, and the performance characteristics of sampling plans (eg, consumer's versus producer's risk), there is often a high probability of a food lot meeting a criterion when tested by a producer failing when tested by a regulatory agency. To reduce this probability, the producer can do a number of things including one or more of the following:

- examine more and/or larger Sample Units (where appropriate, these may be composited for testing) and/or apply tighter limits for food lot acceptability
- use an automated sampling device that takes small product samples frequently and regularly from a production line and composite these—this has been successfully used for salmonella testing in dried milk plants
- select a time or a point in the production process where a contaminant, if present, is most likely to be detected (eg, in food residues on equipment, in environmental samples, or where a contaminant is most likely to be most homogeneously distributed)
- use a variables-based sampling plan.

Purchasing Specification. Such specifications may be between a raw material or ingredient supplier and a food manufacturer, or between a manufacturer and a customer, such as a retailer. The content of a microbiological criterion for these two purposes will be broadly the same and will comprise identification of the foodstuff(s) to which the criterion applies (this should include an agreed definition of a food lot); a listing of organisms and/or toxins to which the foodstuff(s) should comply; the food lot acceptance sampling plan to be applied including limits for each microorganism, metabolite, or toxin; analytical technique to be used (sampling method, procedure for storage of samples, preparation of sample units for analysis and methods of analysis); point(s) of analysis, eg, before a particular processing step, after packaging; frequency of testing (every lot or specified skip lot testing); action(s) to be taken when lot does not meet the microbiological specification (including agreed method of reporting out-of-specification product lots). The testing done to ensure compliance with a buying specification may be done by a laboratory operated by the supplier, the purchaser, or a third party laboratory; it is most important that all concerned are aware of the sampling procedures, the methods of analysis, and the reporting procedures.

The extent to which a microbiological criterion will be applied as part of a purchasing specification should depend first on the microbiological concerns associated with the raw material or product and second, the demonstrable degree of production control exercised by the supplier. For instance, has the supplier's production unit been audited to establish that GMP and quality assurance systems are in place and whether a validated HACCP system is operational? Can control and monitoring records at CCPs be made available to the purchasing company? Third, what is the track record of the supplier? Product from a new supplier will initially require more frequent testing (eg, every food lot) than an established supplier with a good record of compliance and particularly where the supplier's CCP monitoring and verification data are available to the purchaser. If product is to be purchased from a factory where the purchaser has limited or no knowledge of the control procedures that are in place, for instance, because it is located in a relatively inaccessible part of the world, some knowledge can be obtained by asking a supplier to complete a questionnaire asking for details of production methods and control procedures (including management systems). However, information obtained in this way often is incomplete or questionable, so the buyer may have to rely on the use of a lot acceptance sampling plan to check that the product meets the buying specification. In this situation, the purchaser may apply a system of hold and test (the product is not used or dispatched until the results of analysis are available) and apply a more extensive range of tests and/or stricter limits to a lot to provide additional assurance of microbiological acceptability.

A buying specification applied by industry should never form the basis for a legally enforceable microbiological criterion for the following reasons.

- The types of organisms included in a buying specification may be because the food is to be used for a particular purpose (eg, thermophiles in raw materials used in canned foods to be distributed in tropical countries).
- The limits applied in a buying specification will usually be much stricter than those applied in a regulation for a number of reasons (see above), including the need for low count raw materials for an extended shelf life of chill-stored product. Thus, a very tight limit for *L. monocytogenes* may be appropriate in a sampling plan applied to a chill-stored, ready-to-eat product by a purchaser such as a retail store; such a limit would be much tighter than that used in a regulation so that the level of listerias in the product at the end of shelf life does not exceed a safe level.
- The level of sampling applied to a product that is tested on a regular basis in a production plant operating to GMP and applying HACCP may not be the level of sampling that would be appropriate for a food lot, when examined by a third party with no knowledge of the control measures applied during production.

Establishing and Verification of HACCP. Limits for microorganisms or toxins in microbiological criteria may have a useful role in HACCP.[56,65] They may be used in an HACCP study as an indication of the maximum concentrations acceptable in a foodstuff and thus may be used to identify a suitable critical limit for a CCP. However, absence of a limit for a particular pathogen in a recognized criterion should not imply that it should not be considered in an HACCP study as the identification of hazards should always be based on a hazard analysis of an actual food operation (see Chapter 58).

The process of "verification" mostly is defined in the context of its use in HACCP, but it can also apply to verification of GMP. The definition of verification applied by Codex[25] is: "The application of methods, procedures and tests, in addition to monitoring, to determine compliance with the HACCP plan." Verification is defined in this way in other documents on HACCP[39,52] in order to clarify that the process of verification is additional to the monitoring procedure routinely applied to ensure appropriate control at a CCP. Monitoring and control at a CCP are almost entirely achieved by applying nonmicrobiological methods because of the slow response time and poor accuracy of microbiological methods. The process of "validation" is applied to "obtaining evidence that the elements of the HACCP plan are effective."[25] Unlike verification, it is not an ongoing activity and is only intended to support the initial establishment of the HACCP plan.

Although one of the main uses of microbiological criteria within HACCP is in verification, lot acceptance testing, using Attribute or Variables Sampling Plans, may be used to monitor a particularly microbiologically sensitive raw material such as a spice for salmonella. For instance, if this were to be used as a flavoring agent in a ready-to-eat snack product, the spice would not be used until the results of an analysis indicated that it was negative for salmonella, as spices, depending on type, source, and treatment may be contaminated with salmonellas. Thus, testing the ingredient in this instance is an act of monitoring and the critical limit for the CCP (ie, the raw material) is defined as the microbiological criterion. Also, for some products, and particularly where the HACCP study identifies that a hazard may not be reliably controlled to an acceptable level, it may be appropriate to apply a microbiological criterion to an end product as part of production control. In this case, the product is held pending the results of the monitoring process that consists of applying an attribute or variables sampling plan to determine whether the product complies with the established criterion. It is important to recognize that in HACCP, monitoring is distinct from verification as the former is used to routinely monitor that control is achieved at a CCP, whereas verification is an additional procedure aimed at confirming that the HACCP plan provides the intended degree of control over microbiological and other hazards identified in the plan. Thus, verification may be applied to a newly established HACCP plan or to a plan that has been in operation for some time. Many procedures may be used in the process of verification (see Chapter 58), but we are only concerned here with the use of microbiological criteria for this purpose.

One of two strategies may be used if a microbiological criterion is to be used in the verification of HACCP. The first is to follow the advice in the ICMSF book on HACCP,[34] which is to apply a sampling plan that is much more rigorous and searching than that which might be applied in a routinely applied sampling plan, recognizing that it should test the performance of the HACCP plan. This could include taking more samples for analysis, applying additional microbiological tests, and/or applying more strict limits for acceptance. Such rigorous testing would only be done at infrequent intervals and could apply to end-product testing, environmental testing, or microbiological testing at a CCP that would normally be monitored by nonmicrobiological means. The second strategy is to apply trend analysis to the additional microbiological testing and to take more frequent samples for analysis but to use a low sampling rate. Such data could then be subject to standard statistical analysis using control charts such as Shewart or Cusum charts (see Chapters 58 and 60). However, the confidence of decisions on acceptability based on the cumulative data from successive batches of product sampled at a low rate over a period of time remains poor. Thus, it has been estimated that if there is a contamination rate in a food lot of 0.1% (for instance 1 in 1,000 product units are contaminated with salmonella) and if a sampling plan of $n = 5$; $c = 0$; $m = 0$ is applied to one lot, and if the sampling plan is then repeated on an additional 9 and 29 lots, the probability of acceptance (salmonella not detected) is respectively 99.5%, 95.1%, and 86% (Dr. P. Teufel, personal communication 1996). To obtain 95% probability of detecting a contamination level of 0.1% in a food lot, and assuming a Poisson distribution of microorganisms in the food lot, 3,000 production units would need to be examined. Thus verification of HACCP applying microbiological criteria has only limited value[16] unless very large numbers of sample units are examined.

Summary. The potential uses of microbiological criteria by industry are much broader than those of a regulatory authority (Table 65–5). There are significant advantages to industry of establishing their own criteria to meet internal needs and any required in regulations. The meeting of all such requirements usually would be achieved by the application of GMP and HACCP. The use of microbiological criteria for raw material or end-product testing should not be a routine activity unless part of an HACCP-based control program. Microbiological testing may be used more frequently when considering the use of a new supplier or raw material source, introducing a new process or where there is evidence of microbiological contamination of a process or product.

65.4 CONCLUDING REMARKS

For the most part, microbiological criteria have been, and still are, based mainly on technical achievement and not on an objective assessment of need based on utility and a scientifically based assessment of risk. As noted in the introduction to this chapter, the ICMSF[35] developed an approach to establishing microbiological criteria that was based on a form of risk and hazard ranking to establish suitable sampling plans. These plans, despite some limitations inherent in their use, have stood the test of time and deserve the worldwide acceptance that they have achieved. However, since their introduction in the early 1970s, the systems of control of the microbiological safety and quality of food have evolved and the role of microbiological criteria has needed to change from a primary control role to a role essentially supporting the establishment and application of HACCP.

Microbiological criteria should define the levels of specific microbiological hazards that are considered acceptable in a foodstuff for consumer protection. If to be established for the reasons described in this chapter, they should be based on the principles adopted by the Codex Alimentarius Commission.[18] They should communicate to both industry and the regulatory authorities the level of control that must be exercised to ensure the safety and acceptability of a foodstuff. Thus, the establishment of a microbiological criterion has a valuable function. However, as we have noted and discussed in this chapter, their application as a primary means of ensuring that a food is safe to eat or that a production process was properly applied is limited, and conclusions based on their use may be misleading and may only provide a false sense of security to their user. The overriding consideration of whether or not to use microbiological testing as part of a control process should be based on whether or not it will provide necessary additional assurance of food quality or safety.

The use of microbiological risk assessment to understand the significance of microbiological hazards in relation to their probability of causing foodborne illness should enable policy makers concerned with public health aspects of food to better establish measures (including microbiological criteria) and to appropriately assign resources to effect their control. Although in its infancy as a means of establishing the risks associated with microbiological contamination of foodstuffs, microbiological risk assessment is an important first step on the path leading to the establishment of effective international and national food control policies. To this end, the ICMSF has proposed to the Codex Alimentarius Food Hygiene Committee a series of six steps for managing the microbiological hazards associated with foods in international trade based on the documents developed by the Codex Alimentarius Commission. These steps are shown in Exhibit 65–2.

It would be exceptional for industry to undertake a formal microbiological risk analysis for the reasons outlined in the first part of this chapter. Rather industry should encourage the regulatory authorities to carry out in-depth risk assessments and for industry to work with the authorities to identify appropriate risk management options, including Food Safety Objectives.[37] Such options can then be used by industry to develop specific control measures for operations throughout the food chain based firmly on the application of HACCP principles.

Exhibit 65–2 Logic Sequence for the Future Management of Microbiological Hazards for Foods in International Trade

STEP 1: Conduct a risk assessment
Apply the "Principles and Guidelines for the Conduct of Microbiological Risk Assessment" proposed by the Codex Food Hygiene Committee[24]

- The risk assessment provides the scientific basis for risk management decisions.

STEP 2: Conduct a risk management option assessment
Apply the "General Principles of Food Safety Management."[22]

- Consider establishment of an appropriate food safety standard (ie, a food safety objective).

STEP 3: Establish a food safety objective
Food safety objective. This is a statement of the maximum level of a microbiological hazard considered acceptable for consumer protection.

- A food safety objective should be technically feasible.
- The statement should include quantitative value.
- A food safety objective should be developed by a governmental body with a view to reaching consensus for a food in international trade.

STEP 4: The food safety objective should be achieved through the application of:
"The General Principles of Food Hygiene" or product specific codes and "The Hazard Analysis and Critical Control Point (HACCP) System and Guidelines for Its Application"[25]

- It should be confirmed that the food safety objective is achievable.
- The HACCP requirements must be developed separately by the food industry.

STEP 5: Establish microbiological criteria, when appropriate

- Apply "The Principles for the Establishment and Application of Microbiological Criteria for Foods"[25]
- This step should be performed by an expert group of food microbiologists, including experts with experience in the food industry.

STEP 6: Establish acceptance procedures for the food at port of entry

- Apply "Guidelines for the Design, Operation, Assessment and Accreditation of Food Import and Export Inspection and Certification Systems" (Alinorm 97/30A Appendix II)
- Acceptance, for example, could be based on a list of approved suppliers determined by inspection of facilities and operations, certification etc; microbiological testing (if criteria have been established) and/or other testing, eg pH, a_w, or container integrity.
